ABSTRACT

HYDRAULIC MODELING ANALYSIS OF THE MIDDLE RIO GRANDE - ESCONDIDA REACH, NEW MEXICO

Human influence on the Middle Rio Grande has resulted in major changes throughout the Middle Rio Grande region in central New Mexico, including problems with erosion and sedimentation. Hydraulic modeling analyses have been performed on the Middle Rio Grande to determine changes in channel morphology and other important parameters. Important changes occurring in the Escondida reach between 1918 and 2005 were analyzed for this study.

The Escondida reach covers 17.7 miles from the Escondida Bridge to the US Highway 380 Bridge. Spatial and temporal trends in channel geometry, discharge, and sediment have been analyzed. In addition, historic bedform data were analyzed and potential equilibrium conditions were predicted. This study will help facilitate better management of restoration, irrigation, and flood protection efforts.

Aerial photographs, GIS active channel planforms, cross-section surveys, hydraulic model analysis and channel classification methods were used to analyze spatial and temporal trends in channel geometry and morphology. Narrowing of the channel was observed from GIS active channel planforms between 1918 and 2005, with the upstream section of the channel showing the greatest narrowing. Fluctuations were observed in nearly all channel geometry properties. These fluctuations may be caused by a complex response to past channel changes. In addition, the mean bed grain diameter increased slightly from about 0.15 mm to 0.31 mm between 1962 and 2002.

Field observations of bedforms were compiled and compared to the bedforms predicted by van Rijn and by Simons and Richardson. Both methods produced acceptable results, but a large amount of scatter was observed in the data. Wide variability across a single cross section may be the source of the scatter.

Analyses of trends in sediment and water discharge shows a dry period between 1949 and 1979, a wet period between 1979 and 2000, and a dry period between 2000 and 2005. By contrast, the mean daily suspended sediment discharge remained nearly constant. Difference mass curves showed aggradation and degradation that approximately correlated with changes in mean bed elevation.

A variety of approaches were used to predict future equilibrium width and slope conditions. The approaches used include hydraulic geometry equations, hyperbolic and exponential regressions, stable channel geometry, and sediment transport relationships. Several methods predicted an equilibrium width around 300 ft, and Julien-Wargadalam and SAM analysis predicted equilibrium slopes between 0.00065 and 0.00139. Both the equilibrium slope and width predictions seem to provide reasonable estimates of future conditions.

1. Introduction

Since the arrival of the first humans along the Middle Rio Grande River over 10,000 years ago, their activities have had a significant impact on the river as well as on the natural areas surrounding the river. Early Puebloan inhabitants cleared areas of the Bosque to make way for farmland. Later Spanish settlers introduced grazing livestock to the area and continued to clear native riparian forests for both farming and new settlements to accommodate their ever-increasing population. In addition to introducing livestock to the area, Spanish settlers also introduced many exotic plant species that invaded the habitat of native plants. These human impacts, coupled with natural events such as droughts, lead to changes in vegetation types as well as increased soil erosion along much of the Middle Rio Grande (Scurlock 1998).

By the beginning of the 20th century, significant changes had occurred in the Middle Rio Grande Valley. Increased mining, logging, and grazing had destroyed much of the vegetation, resulting in dramatic erosion and a subsequent increase in the sediment load in the River (Scurlock 1998). The increased erosion and sediment load had caused a loss of about 13 percent of the capacity of Elephant Butte Reservoir by the mid 1930's (Clark 1987). The increased sediment load also led to severe aggradation along the River. Between 1880 and 1924, the bed of the river rose 9 feet at San Marcial (Scurlock 1998).

To combat the many problems facing the River, the Middle Rio Grande Conservancy District (MRGCD) was formed in 1923. The purpose of the MRGCD was to "provide flood protection from the Rio Grande, and make the surrounding area hospitable for urbanization and agriculture." Between 1923 and 1935 one storage dam and four diversion dams, as well as 817 miles of drainage and irrigation channels had been constructed by the MRGCD (MRGCD 2006).

The MRGCD's efforts were an initial success. However, the floods of 1941 and 1942 damaged many of the early MRGCD levees, irrigation and drainage systems. Following the Congressional Flood Control Acts in 1948 and 1950, the Bureau of Reclamation and the Army Corps of Engineers repaired and updated the structures originally installed by the MRGCD. New levees and the Cochiti Dam were also constructed to combat flooding and sedimentation problems along the river (MRGCD 2006).

The cumulative effect of centuries of human influence on the Middle Rio Grande caused a dramatic change in the habitat of many native species leading to a decrease in their presence along the river. Dams constructed for flood control purposes have regulated the flow of the river, virtually eliminating the seasonal flooding essential to the reproduction of the Rio Grande silvery minnow and many native trees such as the cottonwood (Bogan et al. 2006, Earick 1999). As a result, aging cottonwoods are being replaced by Russian olive and tamarisk, and the Rio Grande silvery minnow, once found from Espanola, NM to the Gulf of Mexico, is now present in only five percent of its former range (Earick 1999, MRGESACP 2006a). In some years, about ninety-five percent of the Rio Grande silvery minnow population is concentrated in the San Acacia

reach (below the San Acacia diversion dam) of the Middle Rio Grande (MGRCD v. Norton 2002). In addition, habitat reduction has also threatened the southwestern willow flycatcher. In 1994 and 1995 the Rio Grande silvery minnow and the southwestern willow flycatcher, respectively, were placed on the endangered species list in response to their dwindling numbers (MRGESACP 2006b, MRGCD v. Norton 2002).

Today, the Rio Grande runs, as it always has, through a valley caused not by the river, but by the Rio Grande Rift. The rift is formed by the earth's tectonic forces slowly pulling and stretching the Earth's crust, while at the same time, pushing up rock on either side of the rift. Over time, the aggrading nature of the Middle Rio Grande has helped fill the rift by depositing as much as 20,000 feet of sediment in some areas and about 5,000 feet in the Socorro area (Earick 1999, Hawley 1978). Another of the Earth's geological phenomenon is also changing the face of the Middle Rio Grande Valley. The Socorro Magma Body, centered about 12.5 miles upstream of the study reach, is causing an uplift of the valley (Larsen and Reilinger 1983, Ouchi 1983). The center was estimated to have risen at a rate of 1.3 to 2.3 mm/yr between 1951 and 1980. The uplift is causing an increase in slope downstream of the center and a decrease in the slope upstream of the center (Reclamation 2003).

The section of the Middle Rio Grande examined in detail in this report is frequently called the Escondida Reach and stretches 17.7 miles from the upstream extent at the Escondida Bridge to the downstream extent at the US Highway 380 Bridge near San Antonio. Figure 1.1 shows a topographic map of the study reach. Historically, this section of the river has been an aggrading, sand-bed channel showing some areas with a braided planform. However, narrowing of the channel has occurred both before and after the channelization projects completed in the 1950's (Porter and Massong 2004).

Figure 1.1 Location Map and Topographic Map of the Escondida Reach

The objectives of this study of the Escondida Reach include:

- Identifying spatial and temporal trends in channel geometry and morphology. Visual observations of aerial photographs and GIS active channel planforms, cross-section surveys, hydraulic modeling using HEC-RAS, and channel classification methods will be used to identify trends. In addition, changes in bed material were observed from cross-section data.
- Determining the ability of bedform prediction equations to match bedform observations. Field observations of bedforms will be compared with the bedforms predicted by van Rijn (1984) and Simons & Richardson (from Julien 1998).
- Analyzing trends in water and sediment discharge. Mass curves developed from USGS gauge data are used to show changes in the relevant parameters.
- Providing estimates of potential equilibrium slope and width conditions. Potential future conditions are estimated using hydraulic geometry equations, hyperbolic and exponential regressions, stable channel geometry, and sediment transport relationships.

The information presented in this report is divided into ten sections. An introduction to the Escondida reach and the Middle Rio Grande, along with the purpose and objectives of the study, is included in Section 1. Section 2 covers the site description, historical background of the study area, subreach definition, information about available data, and the determination of the channel forming discharge. In Section 3, the geomorphic and river characteristics are discussed. Suspended sediment and water history are the focus of Section 4. Analysis of the active floodplain is in Section 5, and a bedform analysis can be found in Section 6. Section 7 includes an investigation of equilibrium based on hydraulic geometry and sediment transport predictors for the study reach. A discussion of the results of the analysis and a summary of the reports are found in Sections 8 and 9 respectively. Finally, a list of cited references is located in Section 10. Appendices A-E include tables and plots relevant to the morphological assessment of the reach, including hydraulic model output, bed material gradations, and bedform classification. Appendices F and G include model output and other information used in the equilibrium predictor methods.

2. Site Description and Background

The Middle Rio Grande covers about 170 miles of central New Mexico from Cochiti Dam to Elephant Butte Reservoir (Tetra Tech, Inc. 2002). The river has been greatly influenced by humans beginning as early as 10,000 years ago (Scurlock 1998). More recently, the Middle Rio Grande Conservancy District, the Bureau of Reclamation and the Army Corps of Engineers have undertaken numerous projects along the Middle Rio Grande to combat floods and sedimentation problems (MRGCD 2006). The human influences on the river have caused significant habitat loss to native plant and animal species and have prompted detailed study of the Middle Rio Grande.

The 17.7-mile-long Escondida Reach is the subject of this report. The upstream extent of the reach is the Escondida Bridge (River Mile 104.8) north-west of the town of Escondida, NM (Figure 2.1). The downstream extent is the US Highway 380 Bridge (River Mile 87.1) located directly west of the town of San Antonio, NM (Figure 2.3). Historically, this reach has been an aggrading, sand-bed channel with a primarily braided planform, but the channel has narrowed due to human influences and natural processes (Porter and Massong 2004). Figures 2.1 through 2.3 show 2005 aerial photographs of the study reach. These figures show an abundance of arroyos entering the river in subreach 1 and the very straight, narrow planform of subreach 3. The river runs nearly parallel to the low-flow conveyance channel located on the west bank of the river, indicating that the levees protecting the conveyance channel may be influencing the path of the river.

Figure 2.1 2005 Aerial Photo of Subreach 1

Figure 2.2 2005 Aerial Photo of Subreach 2

Figure 2.3 2005 Aerial Photo of Subreach 3

2.1. Subreach Definition

In an effort to better assess the historic changes in the Escondida reach, as well as to make better predictions of possible future conditions, the reach was divided into three subreaches. The subreach definitions were determined by initial assessments of the channel width and planform from GIS aerial photos. In addition, aggradation and degradation based on the minimum channel elevations also helped determine the final delineations. The location of the subreach delineations can be seen in Figure 2.4.

Figure 2.4 Subreach Definitions and Agg/Deg Location

Subreach 1 stretches from the Escondida Bridge to Agg/Deg line 1346, located between Arroyo de la Presilla and Arroyo del Tajo. Subreach 2 stretches from Agg/Deg line 1364 to Agg/Deg 1455. Finally, Subreach 3 stretches from Agg/Deg 1455 to the US Highway 380 Bridge.

2.2. Available Data

The data used in this study was retrieved from a number of different agencies including Reclamation, the United States Geological Survey (USGS), the National Oceanic and Atmospheric Administration (NOAA), and the Middle Rio Grande database compiled at Colorado State University for Reclamation.

2.2.1. Water and Suspended Sediment Data

Historical mean daily discharge data was obtained from two USGS gauges; the San Acacia gauge (08354900), located approximately 11 miles upstream of the study reach, and the San Marcial gauge (08358400), located approximately 18 miles downstream of the study reach. The dates of available discharge data from the USGS website (<http://waterdata.usgs.gov/nm/nwis/rt>) are shown in Table 2.1.

Table 2.1 Available Daily Discharge Data

USGS Gauging Station	Dates
RG Floodway at San Acacia	1958-current
RG Floodway at San Marcial	1949-2006

Two additional gauges are located within the study reach, one at the upstream boundary (Escondida Bridge) and the second at the downstream boundary (San Antonio Bridge). These two gauges only have recent real-time discharge data, not the historical data necessary for this study. An example hydrograph for the San Acacia and San Marcial gauges is shown in Figure 2.5. This hydrograph has a peak near the bankfull discharge of 5000 cfs described later in Section 2.3. The first, longer peak seen between April and June is a result of snowmelt in the Rio Grande headwaters. The second, shorter peak seen in August is the result of an intense summer thunderstorm characteristic of the Middle Rio Grande Valley.

Figure 2.5 Hydrograph for San Acacia and San Marcial Gauges

In addition, daily-suspended sediment data was also available at the San Acacia and San Marcial gauges. Figure 2.6 shows the annual suspended sediment load at each gauge. A blank year indicates that complete sediment data was not available for that year.

Figure 2.6 Annual Suspended Sediment Yield at San Acacia and San Marcial Gauges

Continuous suspended sediment data was not always available for all parameters at all gauges. Table 2.2 gives the dates of continuous, viable data at each gauge. Additional sediment data from 1955 to 2005 was provided by Reclamation (2011). This data set contained yearly suspended sediment totals, while Table 2.2 provides daily suspended sediment load that were obtained from the USGS sediment website (<http://co.water.usgs.gov/sediment/>).

Table 2.2 Available Suspended Sediment Data

	July 1961
	April 1962 - July 1962
	Aug 1962 - Sep. 1962
	March 1963 - Sep. 1996

2.2.2. Bed Material

Bed material data was collected at Socorro range lines (SO-lines) by Reclamation from 1990-2005 (see Figure 2.8). The surveys include grain-size distributions for each sample. The dates and locations of the material collected are displayed in Table 2.3.

Table 2.3 Available Bed Material Data at SO-Lines

Years	SO Line Number									
	1313	1316	1346	1371	1380	1401	1414	1437.9	1450	1470.5
1990								X	X	X
1991					X	X			X	X
1992							X	X		X
1993							X	X		X
1994							X	X		X
1995							X	X		X
1996		X		X			X	X	X	X
1997		X	X	X			X	X	X	X
1998							X	X		X
1999	X	X	X	X			X	X		X
2002							X			
2005							X			X

Additional bed material data was also obtained from the USGS gauging stations at San Acacia and San Marcial. Data were sporadically available from 1966-2004 at the San Acacia gauge and from 1968-2004 at the San Marcial gauge.

The information from the gauging stations was only used in analysis when appropriate bed material data were not available from the SO-line surveys.

2.2.3. Tributary and Arroyo Information

Eight small tributaries enter the Middle Rio Grande in the Escondida reach. The majority of these tributaries are arroyos. The arroyos entering the river include the Arroyo de los Pinos, Arroyo de Tio Bartolo, Arroyo de la Presilla, Arroyo de Tajo, Arroyo de las Canas, and Brown Arroyo. In addition, the Escondida Drain and the North Socorro diversion channel also outfall in the Escondida reach. The location of the tributaries can be seen on the aerial photographs in Figures 2.1 through 2.3.

The role of arroyos in the Middle Rio Grande River is as a primary source of sediment. These arroyos contribute most of the gravel-sized material present in the reach. The sediment contribution occurs mostly during high-intensity summer thunderstorms (Reclamation 2003). The sediment (material) contributed by each tributary varies. For example, the Arroyo de las Canas typically contributes gravel-sized material, while the North Socorro diversion channel contributes mostly sand-sized material (Porter and Massong 2004).

2.2.4. Survey Lines and Dates

Cross-section information were collected by Reclamation using two methods. Agg/Deg lines were surveyed using aerial photography and do not provide detailed information about the channel in any location covered by water at the time of the survey. The average bed elevation was estimated using HEC-RAS and the discharge on the date of the aerial photography. These data sets provide topographic data on parts of the floodplain, not covered by the detailed on-ground surveys. Agg/Deg lines 1313-1476 were used in the hydraulic analysis (see Figure 2.4). This includes one cross-section upstream of the study reach and one cross-section downstream of the study reach. Because the extent of the Agg/Deg lines used does not exactly match the limits of study, the length of the reach used for hydraulic analysis is slightly longer than the actual study reach. Agg/Deg lines are spaced about 500 feet apart and were surveyed in 1962, 1972, 1985, 1992, and 2002.

SO range lines were surveyed by Reclamation beginning in 1987. These surveys provide detailed information about the channel cross-section that is not available from the aerial photographs. Thirty-three SO-lines are located in the reach. Figure 2.7 shows the location of the SO-lines and Table 3.4 shows the dates of available survey data at each SO-line. The SA and SO numbers correspond to the Agg/Deg lines numbers. Appendix A contains cross-section plots of the SO-line data.

2.3. Channel Forming Discharge

2.3.1. Effective Flow

The effective flow in the channel was determined using GeoTool (Raff et al. 2004). This program uses discharge data and sediment data to determine the discharge at which the majority of the sediment in the channel is transported. The program was run twice. One run used the daily discharge data collected at the San Acacia gauge; the second run used the daily discharge data from the San Marcial gauge. Both sets of data were determined to have a lognormal distribution. Slope and width information was obtained from HEC-RAS runs using discharges near the expected effective flow. The bed material diameter information was taken from bed material data collected at the SO-lines throughout the reach.

Yang's sand equation was used to calculate the sediment transport rate. Of the methods available, Yang's sand equation is most applicable based on available input data. The energy slope was estimated from HEC-RAS runs in the same manner as the slope and width information. Temperature and bed material data were obtained from SO-line surveys.

An empirical relationship between discharge and hydraulic radius was developed by running HEC-RAS at a wide range of flows and using regression analysis to determine the relationship. The final input data for the effective flow calculations are shown Table 2.5.

Table 2.5 GeoTool Inputs

Input Parameters	
Slope (ft/ft)	0.00079
d ₅₀ (mm)	0.25
d ₈₄ (mm)	0.62
Characteristic Width (ft)	1044
Yang's Sand Method	
Energy Slope (ft/ft)	0.0093
d ₅₀ (mm)	0.25
Temp (°F)	60
Effective Width (ft)	1044
Regression Equation	$R_h = 0.11Q^{0.37}$
Manning's n	0.022

The GeoTool analysis resulted in effective discharges ranging from about 3000 cfs to 5000 cfs depending upon the number of bins specified, for data to be sorted into. The distribution of flows were divided into a number of “bins”, which span from the minimum discharge to the maximum discharge. The distribution of these bins can be either arithmetically or logarithmically distributed (henceforth called the “type” of binning). The number and type of bins substantially affects the determination of the effective discharge (Raff et al. 2004). The ideal number of bins is the largest number of bins with a minimum number of empty bins (Brown 2006). The effective discharge corresponding to the ideal number of bins was determined to be 4600 cfs for both the San Acacia and San Marcial gauges.

2.3.2. Recurrence Interval

The 2, 5, 7, and 10 year flows were calculated from the annual peak flow information obtained from the San Acacia and San Marcial gauges, which are based on mean daily data. Figure 2.8 and 2.9 show the annual peak flows at San Acacia and San Marcial. Figure 2.10 displays a comparison of the peak flows at the two gauges.

Figure 2.8 Annual peak flow at San Acacia gauge

Figure 2.9 Annual peak flow at San Marcial gauge

Figure 2.10 Comparisons of Annual Peak Flows

The recurrence intervals calculated from the peak flow and corresponding discharges can be seen in Table 2.6.

Table 2.6 Recurrence Interval

Recurrence Interval (years)	Discharge (cfs)	
	SA	SM
10	6,846	6,095
7	6,350	5,584
5	5,984	5,384
2	4,587	3,100

Based on the recurrence interval analysis, the effective discharge is in the approximate range of a 2-year storm event.

2.3.3. *Bankfull Measurements*

Bankfull flow was not calculated directly for the Escondida reach, but a near-bankfull discharge of 5000 cfs was observed by Reclamation in August, 1999 in the San Acacia reach located just upstream of the Escondida reach. In addition, calculations performed by Reclamation in the San Acacia reach estimated the bankfull discharge of 5000 cfs with a recurrence interval between 1.5 and 2.5 years (Reclamation 2003). The recurrence interval calculated by Reclamation corresponds well with the recurrence interval calculated above.

The two reaches (San Acacia and Escondida) are located immediately adjacent to one another. Therefore, their recurrence intervals match well to what the observed bank full was estimated to be, by Reclamation. In addition, the effective discharge calculation performed using Geo Tool also falls within the bankfull estimate. Thus, the 5000 cfs bankfull discharge determined by Reclamation was used in the hydraulic analysis of the Escondida reach.

3. Channel Classification

3.1. Channel Planform Methods

A number of quantitative channel classification methods were investigated to determine the methods most applicable to the Escondida reach. The channel was classified based on slope-discharge relationships, channel morphology methods and the stream power relationships. In addition, a qualitative classification of the channel was also made based on GIS evaluation of aerial photographs.

The channel was classified based on slope-discharge relationships developed by Leopold and Wolman (1957), Lane (from Richardson, et. al 2001), Henderson (1966), and Schumm and Khan (1972). Channel morphology methods developed by Rosgen (1996) and Parker (1976) were also used, along with stream power relationships developed by Nanson and Croke (1992) and Chang (1979).

Two additional methods were also investigated, but found to be not applicable to the Escondida reach. These methods were Ackers and Charlton (1970, Ackers 1982), and van den Berg (1995). Ackers and Charlton (from Ackers 1982) was developed for gravel-bed rivers and van den Berg (1995) was developed for channels with a sinuosity greater than 1.3.

3.1.1. Slope-Discharge methods

Leopold and Wolman (1957) determined a critical slope value, based on discharge, which separates braided from meandering planforms. The following equation shows the slope-discharge relationship:

$$S = 0.6Q^{-0.44}$$

Where S is the critical slope and Q is the channel discharge (cfs). Channels with slopes greater than the critical slope will have a braided planform, while channels with slopes less than the critical slope will have a meandering planform. Straight channels may fall on either side of the critical slope. Leopold and Wolman identified channels with a sinuosity greater than 1.5 as meandering and channels with a sinuosity less than 1.5 as straight. Using the slope-discharge relationship and the critical sinuosity value, channels can be divided into straight, meandering, braided, or straight/braided channels.

Lane (from Richardson et. al 2001) developed a slope-discharge threshold value, κ , calculated by this equation:

$$\kappa = SQ^{0.25}$$

Where S is the channel slope and Q is the channel discharge (cfs). The classification of the stream is based on the value of κ as shown below:

Meandering:	$\kappa \leq 0.0017$
Intermediate:	$0.010 > \kappa > 0.0017$
Braided:	$\kappa \geq 0.010$

These threshold values assume the use of English units. Values of κ are also available for SI units.

Henderson (1966) developed a slope-discharge method that also accounts for the median bed size by plotting the critical slope as defined by Leopold and Wolman against the median bed size. The following equation resulted:

$$S = 0.64d_s^{1.14}Q^{-0.44}$$

Where S is the critical slope, d_s is the median grain size (ft), and Q is the discharge (cfs). For slope values that plot close to this line, the channel planform is expected to be straight or meandering. Braided channels plot well above this line.

Schumm and Khan (1972) developed empirical relationships between valley slope and channel planform based on flume experiments. Thresholds were determined for each channel classification as follows:

Straight:	$S_v < 0.0026$
Meandering Thalweg:	$0.0026 < S_v < 0.016$
Braided:	$0.016 < S_v$

3.1.2. Channel Morphology methods

Rosgen (1996) developed a channel classification method based on entrenchment ratio, width/depth ratio, sinuosity, slope, and bed material. Using these channel characteristics, Rosgen developed eight major classifications and a number of sub-classifications. Figure 3.1, shows Rosgen's method for stream classification.

The Key to the Rosgen Classification of Natural Rivers

KEY to the ROSGEN CLASSIFICATION of NATURAL RIVERS. As a function of the "continuum of physical variables" within stream reaches, values of Entrenchment and Sinuosity ratios can vary by +/- 0.2 units; while values for Width/Depth ratios can vary by +/- 2.0 units.

Figure 3.1 Rosgen Channel Classification Key (Rosgen 1996)

Parker (1976) considered the relationship between slope, Froude number, and width to depth ratio. Experiments in laboratory flumes and observations of natural channels lead to the following channel planform classifications:

Meandering: $S/Fr \ll W/h$
 Transitional: $S/Fr \sim W/h$
 Braided: $S/Fr \gg W/h$

Where S is the channel slope, Fr is the Froude number, and W/h represents the width to depth ratio.

3.1.3 Stream Power methods

Nanson and Croke (1992) used specific stream power and sediment characteristics to differentiate between types of channel planforms. The equation used to determine specific stream power is as follows:

Where ω is specific stream power (W/m^2), γ is the specific weight of water (N/m^3), S is channel slope, and W is channel width (m). Three main classes and twelve sub-classes were developed by Nanson and Croke. Three classifications of

interest in this reach, along with the corresponding specific stream power and expected sediment type, are shown below:

Braided-river floodplains (braided):

$$\omega = 50-300$$

gravels, sand, and occasional silt

Meandering river, lateral migration floodplains (meandering):

$$\omega = 10-60$$

gravels, sands, and silts

Laterally stable, single-channel floodplains (straight):

$$\omega < 10$$

silts and clays

Chang (1979) used data from numerous rivers and canals to develop channel classifications based on stream power. The classifications are presented in terms of valley slope and discharge. Figure 3.2, below, shows the four classification regions defined by Chang for sand streams.

Figure 3.2 Chang's Stream Classification Method Diagram (Chang 1979)

Chang found that at low valley slopes, rivers will have a straight planform. With constant discharge, an increase in valley slope will cause the channel to transform to a braided or meandering planform.

3.2. Channel Planform Results

Visual, qualitative characterization of the channel was performed using channel planforms delineated from aerial photographs using GIS in 1918, 1935, 1949, 1962, 1972, 2001, 2002, 2004, and 2005. See Appendix B for information about the aerial photographs. Aerial photographs for 1985 were not available, so a planform delineation was obtained from the Reclamation database. Figure 3.3 show the historical planforms for the Escondida reach.

Based on visual observations, the historical channel was wide and mildly sinuous, but recent planforms show a relatively straight, narrow channel. Some planforms indicate a tendency toward areas of braiding, especially at low flow. The upstream and downstream extents of the reach have seen the most dramatic shift toward a very straight, non-braided channel. This change may be due to the flow being forced into a confined area under the bridges at the upstream and downstream extents of the reach.

Two of the largest shifts can be seen at the upstream and downstream extents of the reach. Between 1935 and 1949, the channel was shortened slightly on the downstream end of the reach. The bridge at this location was moved upstream. In addition, between 1949 and 1962, the upstream extent of the channel was moved considerably. These channel shifts were not caused by natural channel migration, but by bridge and levee construction.

Figure 3.3 Historical planforms

To obtain the values needed in the quantitative channel classification methods, a HEC-RAS model of the reach was run at the bankfull discharge of 5000 cfs. The model was run in years that Agg/Deg survey information was available. Because the channel bed is not clearly defined in the Agg/Deg surveys, available SO survey line information was added to the models to increase detail. Measurements of the channel and valley lengths were obtained from aerial photos in GIS. Table 3.1 shows the input values obtained from HEC-RAS and GIS. Channel characteristics were averaged for each subreach and the overall reach using weighted averages based on half the distance to the next upstream and downstream cross-sections.

The channel classification for each subreach and the overall reach in the five sets of data analyzed are in Table 3.2. The table shows that none of the methods shows a distinct change in the channel planform over time. The channel morphology methods by Parker (1976) and Rosgen (1996) are the only methods that show variation over time and/or between the subreaches in a given

Table 3.2 Channel Classification Results

year. Leopold and Wolman (1957), Schumm and Khan (1972), and Nanson and Croke (1992) all indicated a straight planform for all subreaches in all years, which is true because the sinuosity in all cases is below 1.5. However, this generalization does not clearly explain the river's condition in this reach. Lane (from Richardson et. al, 2001) and Parker (1976) both classify the channel as in a transitional state between meandering and braided. Parker (1976) indicates an overall tendency toward braiding from 1962-1985 and a tendency toward meandering in 1992 and 2002. Rosgen (1996) classifies the channel as B5c from 1962 to 1985 and as C5c from 1992 to 2002. The B5c classification indicates a channel that is moderately entrenched, with a slope of less than 0.02 and a large width to depth ratio. The C5c classification is similar to the B5c classification except that C5c channels are only slightly entrenched and have well developed floodplains. Henderson (1966) shows a braided classification for all years and subreaches, while Chang (1979) gives a meandering or steep braided classification.

When compared with the observations from the aerial photographs, the methods that indicate a straight or braided channel classification provide the best representation of the actual channel characteristics. Braiding is only seen at low flows, the straight classification given by Leopold and Wolman (1957), Schumm and Khan (1972), and Nanson and Croke (1992) is the most accurate for the bankfull discharge of 5000 cfs. This is predicted by the channel classification methods from 1962 to 2002. The Rosgen's (1996) classifications is based on specific characteristics (i.e. entrenchment ratio, width to depth ratio, sinuosity, slope and channel material), thus this method also results in a reasonable description of the study reach. Based on the Rosgen classification the channel is best described as a C5c or B5c. However, the actual sinuosity in the reach is less than 1.2. Based on the C5c or B5c classification the sinuosity should be greater than 1.2, this is the only discrepancy in the Rosgen classification.

3.3. Sinuosity

3.3.1. Methods

The sinuosity of the Escondida reach, as well as the sinuosity of the three sub-reaches, was measured in GIS from aerial photographs of the reach. The valley length was measured for the entire reach and for each subreach as the straight-line distance between the upstream and downstream extents of the reach at the centerline between lateral constraints. The channel length was measured by estimating the location of the river thalweg based on the aerial photographs and planform delineations. The channel length was divided by the valley length to calculate the sinuosity.

Some difficulty was encountered when estimating the river thalweg due to varying quality of aerial photographs. In addition, aerial photographs were unavailable for 1985, however Reclamation's provided channel planform delineations. The delineation was used to estimate the channel and valley lengths for that year. The upstream and downstream extents of the Escondida reach were both relocated during the period of study. The downstream extent was relocated between 1935 and 1949 by 3%, and the upstream extent was relocated between 1949 and 1962 by 0.03%. The relocation is associated with the bridges moving. This resulted in a valley length that was not identical for all years measured, however this does not change the answer significantly. Table 3.3 shows the valley length and the years

Table 3.3 Change in Valley Length

Year	Valley Length (ft)
1935	76,582
1949	74,206
1962	74,229

3.3.2. Results

As seen in Table 3.4, the overall sinuosity decreased from 1.19 to 1.09 between 1918 and 2005. Sinuosity in all subreaches decreased between 1918 and 1949, and sinuosity decreased only a small amount during the period of levee construction and initial channelization between 1949 and 1962. Although the trend was toward a decreasing sinuosity, there were increases in the total channel sinuosity in 1972, 1992, and 2002. Figure 3.4 shows how the sinuosity changed in each subreach and in the entire reach over time.

Table 3.4 Sinuosity Changes

	1918	1935	1949	1962	1972	1985	1992	2001	2002	2005
Subreach 1	1.13	1.15	1.12	1.10	1.16	1.10	1.09	1.09	1.10	1.09
Subreach 2	1.21	1.14	1.12	1.12	1.11	1.09	1.13	1.12	1.12	1.10
Subreach 3	1.22	1.06	1.04	1.01	1.01	1.02	1.02	1.03	1.04	1.02
Total	1.19	1.13	1.11	1.10	1.12	1.08	1.10	1.10	1.11	1.09

Figure 3.4 Sinuosity

Subreach 3 showed a decrease between 1918 and 1935. The sinuosity of this reach continued a steady decrease until 1985 when the sinuosity began to increase. This increase lasted until 2002, when sinuosity decreased again to its current value. Subreach 2 also began with a trend toward decreasing sinuosity. The sinuosity of subreach 2 followed that of subreach three with the exception of a slight increase seen in 1962. The sinuosity of subreach 1 alternated between increasing and decreasing more than the other reaches. An increase in sinuosity was seen between 1918 and 1935, followed by a decreasing trend that continued until 1962. The increase between 1962 and 1972 was followed by a steady decrease in sinuosity until 2002. In 2002, as in the other reaches, the sinuosity increased, only to decrease again in 2005.

In 1918, the sinuosity of subreach 3 was slightly higher than the other reaches, but following 1935, it remained far less sinuous than the other reaches.

Subreach 1 and subreach 2 tended to have sinuosity values close to each other and close to the overall sinuosity. This may be due to the straightening seen at the downstream extent of the reach extending far into subreach 3. Although relocation and straightening occurred at the upstream extent, it had less of an effect on the sinuosity of subreach 1 because it is much longer than subreach 3.

3.4. Longitudinal Profile

3.4.1. Methods

Thalweg Elevation

The thalweg elevation was calculated as the lowest point in the channel based on the SO-line surveys. Because the SO-line surveys offer more detailed cross section information, they were used instead of the Agg/Deg surveys. SO-line data were only available from 1987-2005.

Mean Bed Elevation

Trends in mean bed elevation were evaluated using the Agg/Deg survey data provided by Reclamation. Reclamation's Technical Service Center in Denver adjusted the cross section data by modifying the instream channel portion by lowering the bed elevation iteratively to minimize the error difference between the observed wetted width from the aerial photography and the HEC-RAS model. The method used to generate the Agg/Deg surveys from aerial photographs results in determination of the mean bed elevation. This elevation was used to show the changes in mean bed elevation through time. Because the SO-lines usually fall at the same location as the Agg/Deg lines, only the Agg/Deg lines were used to analyze the mean bed elevation. The change in mean bed elevation at each cross-section was evaluated, along with the changes in the average mean bed elevation by subreach. The averages calculated for the subreaches are based on weighted averages derived from half the distance between next upstream and downstream Agg/Deg line.

Energy Grade Slope

The energy grade line (EGL) slope for the reach was obtained from HEC-RAS models run at the bankfull discharge of 5000 cfs. The average EGL slope for each subreach and the entire reach was calculated in the same manner as the average mean bed elevation.

Water Surface Slope

The water surface slope between cross-sections was calculated from the water surface elevation at each cross section determined by HEC-RAS and distance between cross-sections. Because the water surface slope was computed as a property of the area between two cross-sections rather than a property of the cross-section itself, the weighting scheme used to calculate the subreach averages was based on the distance to the next downstream cross section.

3.4.2. Results

Thalweg Elevation

Figure 3.5 shows the change of the thalweg elevation at each SO-line over time. Only SO-lines with enough years of sample data to provide useful information about trends were plotted. The cross-sections in subreach 1, SO-lines 1313

through 1360 decrease as much as 5 feet and then increase several feet. In subreach 2, SO-lines 1380 through 1414 have a steadily decreasing trend with an overall degradation of around 5 feet. Then the thalweg elevation in subreach 2, SO-lines 1420 through 1450, alternates between increasing and decreasing with nearly every sample, resulting in little long-term change. In subreach 3, only a temporal change can be observed since only SO 1470.5 had available data. The general trend in subreach 3 is one of an initial degradation of about 5 feet over 7 years, followed by a generally increasing trend for the next 5 years. Two of the data points in cross-section 1470.5 indicate one-year aggradation and degradation of more than 10 feet. This can be associated with the channel filling with sediment and a pilot channel being carved. In addition, the data sampled in 2005 indicate an increase of 10 to 15 feet in just one year. There is a datum shift of 2.4 feet, but this does not explain the 10 plus feet of aggradation. It could be possible that significant deposition of sediment occurred throughout the Escondida Reach in 2005, however this was not observed in the San Acacia Reach directly upstream. Thus the data from 2005 was not considered in the above discussion, because the discrepancy could not be verified.

Figure 3.5 Change in thalweg elevation by SO-line

Figure 3.8 shows the thalweg elevation profile of the entire reach. Because the 2005 indicates an unreasonable amount of aggradation, it was not considered in the analysis of thalweg elevation trends. Subreach 3 has had the most change in since 1987, while subreach 2 seems to have been the most stable in recent years. Subreach 1 has seen some recent degradation of the thalweg elevation, but the changes are not as large as those seen in subreach 3.

Figure 3.6 Thalweg elevation profile

Mean Bed Elevation

Changes in mean bed elevation based on Agg/Deg lines are shown over time in Figure 3.7 for each subreach and for the entire reach.

Figure 3.7 Reach averaged mean bed elevation

Subreach 1 and subreach 2 show an average increase of about 2 feet between 1962 and 1985. The mean bed elevation in these two subreaches then decreases between 1985 and 2002. Subreach 3 follows an opposite trend of first decreasing and then increasing. This is attributed to the river naturally adjusting itself due to the affects of channelization.

The change in mean bed elevation at each Agg/Deg line can be seen in Figure 3.8. Between 1962 to 1972, the reach fluctuated between aggradation and degradation spatially. In subreach 1 the river tends to aggrade, while in subreach 3 the river degrades. Subreach 2 shows some degradation but primarily aggradation. Between 1972 to 1992, the river has a tendency to degrade on both ends of the reach while the center of the reach shows aggradation. Between 1992 to 2002, there is spatial fluctuation. The overall river degrades however there are few cross sections where aggradation is observed. The overall change from 1962 to 2002 is similar to the pattern from 1972 to 1992.

Figure 3.8 Change in mean bed elevations

Energy Grade Slope

Figure 3.9 shows the change in EGL slope with time for each subreach and the entire reach.

Figure 3.9 Energy grade line slope

In 1962 and 1972, the ELG slope for all three subreaches was within 0.0003 ft/ft of one another. In 1985, however, the EGL slope of subreach 3 decreased significantly, but subreaches one and two increased at approximately the same rate. By 2002, subreach 1 and subreach 2 had similar EGL slopes, while the EGL slope for subreach 3 was still far lower.

Water Surface Slope

The average water surface slope by subreach and for the entire reach is shown Figure 3.10.

Figure 3.10 Water surface elevation slope

The water surface slope of subreach 1 showed a decreasing trend from 1962 to 1992 with an increase occurring between 1992 and 2002. Subreach 2 showed an opposite trend with an increase in water surface slope between 1962 and 1985, little change between 1985 and 1992, and a decrease between 1992 and 2002. The water surface slope of subreach 3 was highly variable. This reach showed an increase from 1962 to 1972 followed by a dramatic decrease in 1985. In 1992, the water surface slope increased again to near 1972 levels before falling again in 2002.

3.5. Channel Geometry

3.5.1. Methods

Trends in geometric properties were analyzed from HEC-RAS model runs using the bankfull discharge of 5000 cfs. The HEC-RAS geometry files were available from Reclamation for 1962, 1972, 1985, 1992, and 2002. Each model used 162 cross-sections at a spacing of approximately 500 feet. A Manning's n value of 0.02-0.024 was used for the main channel and a Manning's value of 0.1 was used for the overbank area. Manning's n values, bank station and levee locations, and downstream reach lengths were originally determined by Reclamation. Each geometry file was evaluated and compared to GIS aerial

photography for the corresponding year. Adjustments to the bank stations, levee locations, and reach lengths were made based on engineering judgment to best represent the actual channel conditions.

Channel geometry parameters calculated at each cross section by HEC-RAS include:

Cross-Sectional Area	A
Top Width	W
Wetted Perimeter	P_w
Hydraulic Depth	D
Velocity	V
Froude Number	Fr

The numerical results from the HEC-RAS output can be found in Appendix C. The above geometric parameters and other properties available from HEC-RAS were used to calculate two additional channel geometry properties. These properties include:

Max Depth $D_{max} = \text{Water Surface Elevation} - \text{Minimum Channel Elevation}$
 Width/Depth Ratio $W/D = \text{Top width} / \text{Hydraulic Depth}$

The average values of the eight channel properties were calculated using the weighted averages based on half the distance to the next upstream and downstream cross-sections. This weighted average was also used earlier on the Energy Grade Line (EGL) slope calculations.

3.5.2. Results

Figure 3.12 and Table 3.5 shows the trends in the average cross-sectional area, top width, wetted perimeter, hydraulic depth, maximum depth, channel velocity, Froude number, and width/depth ratio in each subreach and in the overall reach.

Top width, cross-sectional area, and wetted perimeter all follow similar trends. The cross-sectional area and wetted perimeter show nearly identical trends. This is reasonable because the two parameters are a function of the width and depth. The top width and wetted perimeter not only have similar trends; they also have similar magnitudes. This indicates that the channel is very wide compared to the depth.

The trends in the width to depth ratio indicate a general trend toward a deeper, narrower channel until 1992, and a slightly wider, shallower channel in 2002. In addition, the high values of the width to depth ratio further reinforce the idea that the channel is very wide compared to its depth.

1972-1992	1	1273.84	948.22	946.20	(1.55)	0.31	637.72	(0.89)	(0.02)
	2	1171.73	415.51	413.13	0.28	1.78	145.00	0.79	(0.00)
	3	6570.81	1871.56	1868.75	(0.34)	0.29	495.15	(0.65)	(0.03)
	Total	1894.21	776.20	773.90	(0.40)	0.29	351.75	0.03	(0.02)
1992-2002	1	43.68	(37.49)	(36.15)	0.37	0.60	(33.86)	(0.21)	(0.06)
	2	(184.95)	(143.62)	(141.73)	0.09	0.48	(101.82)	0.25	0.01
	3	(1966.83)	(713.07)	(711.00)	0.83	0.48	(257.18)	0.75	0.03
	Total	(355.04)	(185.98)	(184.27)	0.28	0.52	(98.96)	0.17	(0.01)
1962-2002	1	777.64	911.78	910.40	(1.50)	0.03	808.61	(1.75)	(0.07)
	2	(357.61)	(250.05)	(251.24)	0.22	1.62	(189.32)	0.32	(0.01)
	3	5353.17	1233.75	1231.80	0.46	(1.03)	239.61	(0.64)	(0.03)
	Total	734.30	309.45	308.10	(0.29)	0.77	183.81	(0.45)	(0.03)

The hydraulic depth and the maximum depth are also closely related. The hydraulic depth is the depth of a rectangular channel which, when divided by the top width of the channel, gives the cross-sectional area of the channel. The maximum depth is the maximum depth found in the channel. The overall trend for both parameters is very similar. Both parameters show an increase in 1992, followed by a decrease in 2002. This correlates well with the decrease in width in 1992 and the subsequent increase in 2002, because as the channel becomes deeper, it must also narrow to maintain continuity.

The trends in velocity are generally opposite the trends observed in the width to depth ratio. This suggests that as the channel becomes narrower, the velocity in the channel increases. The opposite correlation can also be true. An increased channel velocity may scour the channel bed causing increased depth and decreased width.

The average Froude number in the channel in all subreaches and in all years is well below one, indicating that the flow in the channel is generally in the sub-critical regime. This is expected because supercritical flow would be very difficult to maintain in a mild slope, sand-bed channel. In addition, the general trends seen in the channel velocity are similar to those seen in the Froude number.

3.6. Bend Migration

3.6.1. Methods

General observations of the bend migration in the reach were performed using aerial photographs and channel planform delineations in GIS. Areas of movement were identified visually. The changes at the locations of movement were then measured and further analyzed using GIS.

3.6.2. Results

Observations made of recent bed migration indicate that since 1992, very little movement has occurred in the reach. However, observation of bend migrations since 1962 indicates that movement occurred between 1962 and 1992. Table 3.6 shows the locations of significant movement for each time period analyzed. The magnitude and direction of the movement is also included.

Table 3.6 Bed Migration

Year	Agg/Deg Number	Movement	
		Magnitude (ft)	Direction
1985-1992			
	1326-1332	330	R
	1333	120	L
	1352	100	R
	1376	220	L
	1471	150	R
1972-1985			
	1326	200	L
	1363	240	R
	1397-1405	300	L
	1413	120	L
	1421	100	R
	1467	100	L
1962-1972			
	1326	390	R
	1343	295	L
	1347	335	R
	1355	215	R
	1375	250	L
	1378-1386	590	R
	1419-1426	850	R

A few locations showed either very large movement in a single observation period or continued movement over several observation periods. Figure 3.12 shows the progressive channel location near Agg/Deg 1326, Figure 3.13 shows the 590 foot movement observed between Agg/Deg 1378 and Agg/Deg 1386 between 1962 and 1972, and Figure 3.14 shows the 850 foot migration of Agg/Deg 1419-1426 between 1962 and 1972.

Figure 3.12 Bend migration at Agg/Deg 1326

Figure 3.13 Bend migration at Agg/Deg 1378-1386

Figure 3.14 Bend migration at Agg/Deg 1419-1426

The migration of the bends show why the channel sinuosity has slightly decreased and a once wide channel with a tendency to braid at low flows is now more straight and narrow.

3.7. Material Analysis

3.7.1. Methods

The bed material surveys taken at SO-lines were used to determine the median bed grain size for each subreach. When appropriate data was not available at the SO-lines, bed material from the San Acacia and San Marcial gauges was used. In both 1962 and 1972, bed material data was not available, so the grain sizes from the closest available years were used. When SO-line data was used, the median grain size for the subreach was calculated using a weighted average based on the distance between SO-lines. The gauge data that was most similar to the available SO-line data was used in the absence of SO-line data. Grain size classification was determined using Figure 3.15 from Julien (1998).

Class name	Size range	
	mm	in.
<i>Boulder</i>		
Very large	4,096–2,048	160–80
Large	2,048–1,024	80–40
Medium	1,024–512	40–20
Small	512–256	20–10
<i>Cobble</i>		
Large	256–128	10–5
Small	128–64	5–2.5
<i>Gravel</i>		
Very coarse	64–32	2.5–1.3
Coarse	32–16	1.3–0.6
Medium	16–8	0.6–0.3
Fine	8–4	0.3–0.16
Very fine	4–2	0.16–0.08
<i>Sand</i>		
Very coarse	2.000–1.000	
Coarse	1.000–0.500	
Medium	0.500–0.250	
Fine	0.250–0.125	
Very fine	0.125–0.062	
<i>Silt</i>		
Coarse	0.062–0.031	
Medium	0.031–0.016	
Fine	0.016–0.008	
Very fine	0.008–0.004	
<i>Clay</i>		
Coarse	0.004–0.0020	
Medium	0.0020–0.0010	
Fine	0.0010–0.0005	
Very fine	0.0005–0.00024	

Figure 3.15 Grain size classification (Julien 1998)

3.7.2. Results

Figure 3.16 shows the change in grain size in each subreach. While the entire reach remains in the range of grain sizes for sand, there has been an overall increase in grain size in recent years.

Figure 3.16 Bed material mean grain size

The bed material types are summarized in Table 3.7. The bed material size was obtained from SO-line surveys where available. When SO-line surveys were not available, San Acacia gauge data were used for subreach 1, San Marcial gauge data were used for subreach 3, and an average of San Acacia and San Marcial gauge data were used for subreach 2.

Table 3.7 Bed material type

Subreach	1962	1972	1985	1992	2002
1	Fine Sand	Very Fine Sand	Fine Sand	Fine Sand	Medium Sand
2	Fine Sand	Very Fine Sand	Fine Sand	Medium Sand	Medium Sand
3	Fine Sand	Very Fine Sand	Very Fine Sand	Fine Sand	Fine Sand
Total	Fine Sand	Very Fine Sand	Very Fine Sand	Fine Sand	Medium Sand

The bed material classification has been, increased from very fine sand in 1972 to medium sand in 2002. Average particle size distributions for each year are shown in Figure 3.17. This data were obtained from the San Marcial gage. The particle size distribution also indicates a recent trend toward increasing grain size. Particle-size distributions for each year and subreach are shown in Appendix D.

Figure 3.17 Bed material particle size distributions

4. Suspended Sediment and Water

Single and double mass curves were used to show trends in water discharge, suspended sediment discharge, and suspended sediment concentration. A difference mass curve was developed to show trends in suspended sediment continuity. Suspended sediment continuity compares the amount of sediment entering the reach versus the amount of sediment leaving the reach. Discharge and suspended sediment data were compiled from the USGS gauging stations at San Acacia and San Marcial. There were some large gaps in available data. When data were not available for one or both of the elements under consideration, the date was excluded from the cumulative analysis.

4.1. Methods

Trends in water and suspended sediment discharge were displayed in single mass curves for each gauge. These graphs show cumulative discharge versus time and cumulative suspended sediment discharge versus time. Suspended sediment discharge versus water discharge was graphed in a double mass curve to show the trends in suspended sediment concentration for both the San Acacia and San Marcial gauges.

To develop the difference mass curve for the suspended sediment continuity analysis, the cumulative difference between the San Acacia gauge, located upstream of the study reach, and the San Marcial gauge, located downstream of the study reach, was plotted versus time. A negative slope shows that more suspended sediment is leaving the reach than entering the reach. A positive slope shows that more suspended sediment is entering the reach than leaving the reach. The contributions of arroyos along the reach were not accounted for, so more sediment may have entered the reach than was recorded by the San Acacia gauge. In addition, because both gauges are located a considerable distance from the study reach, the suspended sediment readings taken at the gauges should be an indication but are likely not completely representative of the true amount of suspended sediment entering and leaving the reach.

4.2. Results

4.2.1. Single Mass Curves

The single mass curve for water discharge is shown in Figure 4.1. Both the San Acacia (SA) and San Marcial (SM) gauges have similar flow trends. Both curves show breaks around 1979 and 2000. In about 1979, the discharge increased from approximately 600 cfs to over 2000 cfs. A similar increase in discharge was observed in the San Felipe, Cochiti, and Rio Puerco reaches (Bauer 2000, Novak 2006, Vensel et al. 2005). However, the increase in discharge was not as great as in the Escondida reach. At the break around the year 2000, the gauge at San Acacia decreased from 2900 cfs to 1000 cfs, and the gauge at San Marcial

decreased from 2200 cfs to 750 cfs. Table 4.1 shows the average discharge for each period displayed on the graph.

Figure 4.1 Water Discharge Single Mass Curve

Table 4.1 Water Discharge

Gauge	Years	acre-ft/day	acre-ft/year	R ² value
San Acacia	1958-1979	522	190,530	0.98
	1980-1999	2856	1,042,440	0.99
	2000-2005	1055	385,075	0.93
San Marcial	1949-1978	621	226,665	0.94
	1979-2000	2263	825,995	0.99
	2001-2005	740	270,100	0.84

Figure 4.2 shows the single mass curve for suspended sediment discharge at the San Acacia and San Marcial gauges. The suspended sediment discharge at the two gauges does not correlate as well as the water discharge. The San Marcial gauge has a much higher suspended sediment discharge than the San Acacia gauge from 1956 until about 1968. From 1968 to 1991, the two gauges both have a suspended sediment discharge of about 10000 tons/day. From 1991 to 1996, the San Marcial gauge again shows a much higher suspended sediment discharge.

Figure 4.2 Suspended Sediment Discharge Single Mass Curve

Table 4.2 shows the average suspended sediment discharge for the periods shown on the graph. The R^2 value for each trend line is also shown.

Table 4.2 Suspended Sediment Discharge

Gauge	Years	tons/day	ton/year	R^2 value
San Acacia	1959-1967	6,062	2,212,630	0.94
	1968-1975	9,172	3,347,780	0.92
	1976-1996	10,066	3,674,090	0.99
San Marcial	1956-1959	35,276	12,875,740	0.88
	1960-1989	10,232	3,734,680	0.98
	1992-1995	16,707	6,098,055	0.98

4.2.2. Double Mass Curves

A double mass curve was developed at each gauge to show the changes in suspended sediment concentration over time. Figure 4.3 shows the two double mass curves.

Figure 4.3 Suspended Sediment Concentration Double Mass Curve

From 1959 to 1978, the two curves are very similar, with an average suspended sediment concentration around 13,000 mg/L. Around 1978, both curves break, and the suspended sediment concentration drops to about 3000 mg/L. The concentration at the San Acacia gauge remains at about 3000 mg/L through the end of the available data. The San Marcial gauge, however, shows an increase in suspended sediment concentration from 3000 mg/L to 4500 mg/L around 1990. Table 4.3 shows the average concentration as well as the R^2 values for each segment of the graph.

Table 4.3 Suspended Sediment Concentration

Gauge	Years	tons/acre-ft	mg/L	R^2 value
San Acacia				
	1959-1978	17.9	13165	0.97
	1979-1996	3.58	2633	0.98
San Marcial				
	1956-1977	17.21	12657	0.97
	1978-1989	4.16	3060	0.92
	1990-1995	6.2	4560	0.98

4.2.3. Difference Mass Curve

The daily difference mass curves are shown in Figure 4.4. It is temporal and spatial representation of the increases and decreases in the suspended sediment volume present in the reach over time

Figure 4.4 Suspended Sediment Difference Mass Curve

When more sediment is entering the reach than leaving the reach, aggradation is expected to occur because the sediment inflow that does not exit the reach must remain in the reach. Conversely, when more sediment is leaving the reach than entering, degradation of the channel is expected because the extra sediment leaving the reach is probably being eroded from the channel bed and banks. While arroyos and bank erosion could contribute some of the extra sediment, much of it is probably being mined from the bed.

The graph shows that from 1960 to 1973, more sediment was entering the reach than was leaving the reach indicating a trend toward aggradation. This trend reversed from 1973 to 1983, with more suspended sediment leaving the reach than entering the reach, indicating a trend toward degradation. The trend reversed towards aggradation from 1983 to 1989, and returned to degradation from 1989 to 1995.

Based on the maximum sediment accumulation in the reach, the river should have aggraded by about 10 feet between 1960 and 1973, degraded by 6 feet between 1973 and 1983, aggraded by about less than a foot between 1983 and 1989, and finally degraded by about 7 feet between 1989 and 1995. These amounts of aggradation and degradation are much higher than the amounts of aggradation and degradation actually observed in the cross-section surveys.

The average observed values of aggradation and degradation were between 2 feet and 4 feet.

5. Floodplain Analysis

Observations by Reclamation indicate that an extended floodplain becomes active in the lower portion of the Escondida reach. The extent of the floodplain and the discharge at which the floodplain becomes inundated were investigated.

5.1. Methods

HEC-RAS was used to determine the top width at each cross-section at a series of discharges ranging from 1000 cfs to 6000 cfs. Initial observations from the HEC-RAS data showed two distinct regions of significant floodplain inundation. The average top width in each area was plotted versus discharge for each year of cross-section data to determine the discharge at which the floodplain becomes active. The floodplain becomes active when the top width becomes much greater with a small increase in discharge.

5.2. Results

The first area of interest stretches from about Agg/Deg 1406 to Agg/Deg 1418. The second area of interest stretches from about Agg/Deg 1456 to Agg/Deg 1476. Figures 5.1 and 5.2 show the top width vs. discharge for the two areas of interest and are both based on distance weighted averages.

Figure 5.1 Top width vs. discharge for Agg/Deg 1406-1418

Figure 5.2 Top width vs. discharge for Agg/Deg 1456-1476

Both graphs show that the top width increases sharply around 3000 cfs, indicating that the floodplain becomes active in both areas of interest at about 3000 cfs. A discharge of 3000 cfs has a recurrence interval of less than 2 years. Based on this information, the floodplain will be inundated when the flows exceed a 2-year return period. The width increases by approximately 2 to 13 times between 3,000 cfs to 6,000 cfs.

6. Bedform Analysis

6.1. Methods

Two methods for predicting bedforms were selected for use in this analysis. The methods were developed by Simons and Richardson (from Julien 1998) and van Rijn (1984).

Simons and Richardson (from Julien 1998) performed laboratory experiments to develop a bedform prediction method based on stream power and median grain size diameter.

Stream power:

Where τ_o (lb/ft²) is shear stress, V (ft/s) is velocity, γ (lb/ft³) is the specific weight of water, q (ft²/s) is unit discharge and S is channel slope. Figure 6.1 shows the region where each bedform is expected based on the observations from Simons and Richardson's experiments.

Figure 6.1 Bedform classification by Simons and Richardson (from Julien 1998)

van Rijn (1984) developed a bedform prediction method based on the dimensionless grain diameter and transport-stage parameter.

Dimensionless grain diameter:
$$d_* = d_{50} \left[\frac{(G-1)g}{\nu^2} \right]^{1/3}$$

Where d_* is the dimensionless grain diameter, d_{50} (ft) is the median grain diameter, G is the specific gravity of the sediment and ν (lb*s/ft²) is the kinematic viscosity of water.

Transport-stage parameter:
$$T = \frac{\tau_*' - \tau_{*c}}{\tau_{*c}}$$

Where T is the transport-stage parameter, τ_*' is the grain Shield's parameter, and τ_{*c} is the critical Shield's parameter. Figure 6.2 shows the bedforms expected based on van Rijn's method.

Figure 6.2 Bedform classification by van Rijn (1984, from Julien 1998)

Bedform data were collected by Reclamation at a number of SO-lines between 1990 and 1995. The dominant bedform was selected from the actual field notes as the bedform that covered the largest portion of the main flow area in a cross-section. The expected bedforms at each location were calculated using HEC-RAS, the discharge recorded at the San Acacia and San Marcial gauges on the dates the bedform data were collected, and bed material data. When possible, bed material samples taken at the same time as the bedform observations were used in the calculations. When this information was not available, bed material samples from the nearest SO-line were used. The predicted bedforms were then compared with the dominant bedform at each cross-section to determine the ability of the methods to correctly predict bedforms on the Middle Rio Grande.

6.2. Results

The bedform type observed at each location was plotted on the charts developed by Simons and Richardson and van Rijn based on the calculations performed for each method. Figures 6.3 – 6.6 show each of the four bedform types plotted on both graphs.

Figure 6.3 Observed ripples plotted on graphs from Simons and Richardson (L) and van Rijn (R) (after Julien 1998)

Figure 6.4 Observed dunes plotted on graph from Simons and Richardson (L) and van Rijn (R) (after Julien 1998)

Figure 6.5 Observed transition bedforms plotted on graph from Simons and Richardson (L) and van Rijn (R) (after Julien 1998)

Figure 6.6 Observed antidunes/plane bed plotted on graph from Simons and Richardson (L) and van Rijn (R) (after Julien 1998)

Figures 6.3 – 6.6 show that the predicted bedforms match reasonably well with the predicted bedforms, but the plots show wide scatter. Antidunes were the most reliably predicted bedforms, while lower regime bedforms such as ripples and dunes were difficult to predict correctly. This can be attributed to the fact that observations are subjective, and the difficulty in predicting bedforms can be associated with not having reliable methods for field observations of bedforms.

A likely explanation for the discrepancy between the predicted and observed bedforms is the high variability in important parameters such as flow depth, slope and velocity across a cross-section. There was spatial variability can cause several different bedforms to exist in a single cross-section, which is observed in the field. The prediction methods are unable to account for the variability within the cross-section because they are based on cross-section average properties.

Figure 6.7 shows a typical cross-section with the bedform observations indicated on the cross-section. See Appendix E for the field notes for this cross-section. The width/depth ratio for this cross-section is about 400. This is typical of the Escondida reach and further explains the high variability in the cross-sections. The discharge at this cross-section was about 4400 cfs on the day of the survey. Simons and Richardson predicted antidunes and van Rijn predicted upper regime bedforms for this location. While upper regime bedforms were observed at the cross-section, lower regime bedforms were also observed. Both the upper

and lower regime bedforms were present in the main flow area of the channel and both occupied similar portions of the cross-section. Additional example cross-sections can be found in Appendix E.

Figure 6.7 Typical cross-section with bedforms

7. Equilibrium State Predictors

7.1. Hydraulic Geometry

7.1.1. Methods

Several hydraulic geometry equations were used to determine the equilibrium channel width. These methods use channel characteristics such as channel width and slope, sediment concentration, and discharge. All of the equilibrium width equations were developed in simplified conditions such as man-made channels.

Julien and Wargadalam (1995) used the concepts of resistance, sediment transport, continuity, and secondary flow to develop semi-theoretical hydraulic geometry equations.

$$\begin{aligned}h &= 0.2Q^{2/(5+6m)} d_s^{6m/(5+6m)} S^{-1/(5+6m)} \\W &= 1.33Q^{(2+4m)/(5+6m)} d_s^{-4m/(5+6m)} S^{-(1+2m)/(5+6m)} \\V &= 3.76Q^{(1+2m)/(5+6m)} d_s^{-2m/(5+6m)} S^{(2+2m)/(5+6m)} \\ \tau^* &= 0.121Q^{2/(5+6m)} d_s^{-5/(5+6m)} S^{(4+6m)/(5+6m)} \\ m &= \frac{1}{\ln\left(\frac{12.2h}{d_{50}}\right)}\end{aligned}$$

Where h is the average depth, W (m) is the average width, V (m/s) is the average one-dimensional velocity, and τ^* is the Shield's parameter, and d_{50} (m) is the median grain size diameter.

Simons and Alberston (1963) used five sets of data from canals in India and America to develop equations to determine equilibrium channel width. Simons and Bender collected data from irrigation canals in Wyoming, Colorado and Nebraska. These canals had both cohesive and non cohesive bank material. Data were collected on the Punjab and Sind canals in India. The average bed material diameter found in the Indian canals varied from 0.43 mm in the Punjab canals to between 0.0346 mm and 0.1642 mm in the Sind canals. The USBR data was collected in the San Luis Valley in Colorado and consisted of coarse non-cohesive material. The final data set was collected in the Imperial Valley canal system, which have conditions similar to those seen in the Indian canals and the Simons and Bender canals (Simons and Albertson 1963).

Two figures were developed by Simons and Albertson to obtain the equilibrium width. Figures 7.1 and 7.2 show the relationships between wetted perimeter and discharge and average width and wetted perimeter, respectively.

Figure 7.1 Variation of wetted perimeter P with discharge Q and type of channel (after Simons and Albertson 1963)

Figure 7.2 Variation of average width W with wetted perimeter P (after Simons and Albertson 1963)

Blench (1957) used flume data to develop regime equations. A bed and a side factor (F_s) were developed to account for differences in bed and bank material.

$$W = \left(\frac{9.6(1 + 0.012c)}{F_s} \right)^{1/2} d^{1/4} Q^{1/2}$$

Where W (ft) is channel width, c (ppm) is the sediment load concentration, d (mm) is the median grain diameter, and Q (cfs) is the discharge. The side factor, $F_s = 0.1$ for slight bank cohesiveness.

Lacey (from Wargadalam 1993) developed a power relationship for determining wetted perimeter based on discharge.

$$P = 2.667Q^{0.5}$$

Where P (ft) is wetted perimeter and Q (cfs) is discharge. For wide, shallow channels, the wetted perimeter is approximately equal to the width.

Klaassen-Vermeer (1988) used data from the Jamuna River in Bangladesh to develop a width relationship for braided rivers.

$$W = 16.1Q^{0.53}$$

Where W (m) is width, and Q (m^3/s) is discharge.

Nouh (1988) developed regime equations based on data collected in extremely arid regions of south and southwest Saudi Arabia.

$$W = 2.83 \left(\frac{Q_{50}}{Q} \right)^{0.83} + 0.018(1 + d)^{0.93} c^{1.25}$$

Where W (m) is channel width, Q_{50} (m^3/s) is the peak discharge for a 50 year return period, Q (m^3/s) is annual mean discharge, d (mm) is mean grain diameter, and c (kg/m^3) is mean suspended sediment concentration.

Table 7.1 shows the input values used to estimate channel width from the hydraulic geometry equations. The peak discharges for a 50-year return period were taken from Bullard and Lane (1993). The average sediment concentrations were obtained from the double mass curves (see Figure 4.3) developed for the San Acacia and San Marcial gauges. Suspended sediment data was only available until 1995, so all suspended sediment concentrations after 1995 were extrapolated from the double mass curves.

An empirical width relationship was developed for the Escondida reach based on active channel widths determined from GIS channel planforms and peak flows for the 5 years prior to the survey date (Knighton 1998). Knighton (1998) suggests that it is the high magnitude, low frequency floods that may control the channel form in arid-zone rivers where the flow regime is very variable. For the hydraulic geometry equations, the peak discharge from the 5 years prior to the survey was used. Peak flows for the relationship were obtained from the gages located the San Acacia and San Marcial gauges. The resulting power relationship takes the form:

$$W = aQ^b$$

Where W (ft) is channel width and Q (cfs) is peak discharge. Table 6.2 shows the input values used to develop the empirical width relationship for the Escondida reach.

Table 7.2 Escondida empirical width-discharge inputs

Year	Average 5-year peak discharge (cfs)	GIS widths (ft)			
		Subreach 1	Subreach 2	Subreach 3	Overall

2005	3312	366	498	305	431

7.1.2. Results

The equilibrium channel widths predicted by the hydraulic geometry equations are shown in Table 7.3. All methods except Blench tend to under predict the channel width determined from HEC-RAS runs at 5000 cfs. Blench tends to over predict the channel widths determined from HEC-RAS, but shows the best overall agreement of the methods used to estimate the equilibrium channel width. This does not necessarily mean that Blench is the best predictor of equilibrium width because the channel was likely not in equilibrium between 1962 and 2002. Four methods, Simons and Albertson, Noh, Lacey, and Julien-Wargadalam, predict similar equilibrium channel widths ranging from about 200 feet to about 300 feet. These methods may be a better indication of the expected equilibrium channel width because of their similar results. The channel is tending toward the narrower width predicted by the four methods discussed, but it is still much wider than the predicted equilibrium.

Julien-Wargadalam was also used to predict the equilibrium slope of the channel. Table 7.4 shows the predicted equilibrium slope and the observed channel slope for each subreach and the total reach between 1962 and 2002.

Table 7.4 Equilibrium slope predictions with Q = 5000 cfs

		1962	1972	1985	1992	2002
Observed Slope	1	0.00094	0.00089	0.00084	0.00076	0.00078
	2	0.00078	0.00080	0.00087	0.00081	0.00077
	3	0.00055	0.00070	0.00051	0.00072	0.00076
	Total	0.00080	0.00082	0.00081	0.00078	0.00077

	2	0.00051	0.00035	0.00042	0.00098	0.00113
	3	0.00048	0.00033	0.00031	0.00089	0.00083
	Total	0.00051	0.00034	0.00044	0.00083	0.00117

The results of the equilibrium slope calculations indicate that the channel had a steeper slope than the predicted slope in 1962, 1972 and 1985. In 1992, however, the observed channel slope closely matches the predicted equilibrium slope. In 2002, the early trend is reversed with the predicted channel slope being steeper than the observed channel slope.

Figure 7.3 shows the plot and regressions used to find the empirical equations for the reach. The non-vegetated active channel width were measured using the GIS platforms (Section 3) and plotted against the 5-year average peak flow. Regressions were then developed for each subreach and the total reach. 1962 was the first year used in the regression because including data prior to 1962 would have resulted in regressions that predicted decreasing width with increasing discharge.

Figure 7.3 Escondida empirical width-discharge relationships

The results of the equilibrium width calculations performed using the empirical equation developed for the Escondida reach are shown in Table 7.5 along with the non-vegetated active channel widths.

Table 7.5 Escondida empirical width-discharge results

		1962	1972	1985	1992	2001	2002	2005
Average 5-year peak discharge (cfs)		3676	2644	6321	4638	2937	2344	3312
GIS Width (ft)	1	919	619	671	353	362	334	366
	2	415	274	645	529	569	436	498

	Total	548	376	609	442	468	381	431
Predicted Width (ft)	1	490	430	609	538	448	409	470
	2	478	404	630	538	426	380	453
	3	263	242	303	279	248	234	256
	Total	468	407	587	516	426	387	448

The predicted widths closely match the measured widths in all subreaches and in all years. The empirical equations may be good indicators of the actual expected width at a given discharge because they are based on the historical conditions rather than an ideal, equilibrium state. These equations, however, may not be reliable in predicting the equilibrium width of the channel.

7.2. Width Regression Model

7.2.1. Methods

Hyperbolic Model

The downstream effects of dams on alluvial rivers were studied by Williams and Wolman (1984). They found a hyperbolic equation to describe the changes in channel width with time.

$$\frac{1}{Y} = C_1 + C_2 \frac{1}{t}$$

Where C_1 and C_2 are empirical coefficients, t is the time in years after the initial change in the channel, and Y is the relative change in channel width and is equal to the ratio of the initial width (W_i) to the wide at time t (W_t). The coefficients may be a function of channel characteristics such as discharge and boundary material.

A hyperbolic equation was fit to the data from the each subreach. The initial time ($t=0$) was assumed to be the first year a narrowing trend was observed in the channel. The initial year was different in each subreach and in the total reach. To adjust the equations to an origin of 0, 1.0 was subtracted from the relative width ratio (W_t/W_i) before the regression was fit to the data. The constants C_1

and C_2 were determined by setting the R^2 of the regression as close to one as possible.

Exponential Model

Richard et al. (2005) developed prediction equations for active channel width, total channel width, migration rate and lateral mobility based on data collected in the Cochiti reach of the Middle Rio Grande and verified by data from four rivers including the Jemez river, the Arkansas river, Wolf creek and the North Canadian river. An exponential regression equation was developed to describe channel width as a function of time.

$$W(t) = W_e + (W_i - W_e)e^{-kt}$$

Where W_e is the equilibrium width, W_i is the channel width at the initial time, k is the rate of decay, and t is time after the initial time.

The exponential equation was fit to the GIS active channel width beginning in the first year showing a trend toward decreasing width. The decay constant k , and the equilibrium width, W_e , were determined by setting the R^2 of the exponential regression equation as close to one as possible. Table 7.6 shows the input information for the hyperbolic and exponential regression equations.

Table 7.6 Hyperbolic and exponential regression input

Subreach 1

7.2.2. Results

Four hyperbolic and four exponential equations were developed for the Escondida reach. Figures 7.4 – 7.7 show the regression curves for each subreach and the total reach. All of the graphs start in the initial year and continue through 2020.

Figure 7.4 Hyperbolic and exponential regressions – subreach 1

Figure 7.5 Hyperbolic and exponential regressions – subreach 2

Figure 7.6 Hyperbolic and exponential regressions – subreach 3

Figure 7.7 Hyperbolic and exponential regressions – total reach

As shown in Figures 7.4 – 7.7, the hyperbolic and exponential regression equations produce very similar results. Overall, the exponential regression seems to produce a smoother regression curves.

Table 7.7 shows the hyperbolic regressions for each subreach, along with the predicted width in 2020 and the predicted equilibrium width. The widths predicted in 2020 are reasonable for all reaches and, in most cases, are near the predicted equilibrium width. In subreach 1, the equilibrium width is negative. This indicates that this equation is not a reliable predictor of the ultimate equilibrium width of the channel, but it seems to be a reasonable predictor of the 2020 width. Additional data should be added to the regression equation for subreach 1 as they become available to better refine the equation for long-term predictions.

Table 7.7 Hyperbolic regression equations and predicted widths

Subreach	R ²	Regression Equation	W ₂₀₂₀ (ft)	W _e (ft)
1	1.00	$\frac{W_t}{W_i} = \frac{t}{-0.95t - 18.34} + 1$	277	-79
2	1.00	$\frac{W_t}{W_i} = \frac{t}{-3.55t - 15.81} + 1$	484	463
3	1.00	$\frac{W_t}{W_i} = \frac{t}{-30.64t - 2.33} + 1$	292	292
Total	1.00	$\frac{W_t}{W_i} = \frac{t}{-1.62t - 4.13} + 1$	439	416

Table 7.8 shows the exponential regression equations and predicted equilibrium widths. All of the equations are able to produce reasonable equilibrium widths. The equilibrium widths predicted by the exponential regression are nearly identical to the equilibrium widths predicted by the hyperbolic regression, indicating that these methods may produce good predictions of the equilibrium channel width.

Table 7.8 Exponential regression equations and predicted widths

Subreach	R ²	Regression Equations	W _e (ft)
1	0.97	$W(t) = 296 + 1295e^{-0.045t}$	296
2	0.64	$W(t) = 494 + 151e^{-0.189t}$	494
3	0.10	$W(t) = 289 + 13e^{-0.117t}$	289
Total	0.90	$W(t) = 452 + 629e^{-0.164t}$	452

7.3. Sediment Transport

7.3.1. Methods

The equilibrium slope of the channel was estimated using sediment transport equations. Equilibrium is achieved when the incoming suspended sediment matches the sediment capacity of the reach. When supply and capacity are equal, the channel should not aggrade or degrade and a relatively constant slope should be maintained during lateral migration processes. The incoming sediment supply for each subreach was estimated using the Bureau of Reclamation Automated Modified Einstein Procedure (BORAMEP) and Psands programs. The channel slope was then varied in HEC-RAS until the calculated sediment transport capacity was within 20% of the incoming sediment supply.

The incoming sediment supply for subreach 1 was estimated using the BORAMEP). Suspended sediment and bed material gradations we obtained from the San Acacia gauge between 1990 and 2004. In addition, channel geometry, flow conditions, and suspended sediment concentration were also obtained at the San Acacia gauge for the dates of the suspended sediment and bed material samples. The input and output from BORAMEP can be found in the Appendix E. The total sand-sized sediment load calculated by BORAMEP was plotted vs. discharge. A power-law formula was fit to the data to obtain a regression used for estimating the incoming sediment load in subreach 1.

Psands was used to estimate the incoming sand-size sediment load for subreaches 2 and 3. The sediment load was calculated by Reclamation using Pasands for data collected at SO-lines between 1987 and 1996. A power-law formula was fit to a plot of sediment load vs. discharge to obtain an estimate of the incoming sand-sized sediment load.

HEC-RAS calculates sediment transport capacity using several different methods including those developed by, Ackers & White, Engelund & Hansen, Laursen, Meyer-Peter & Muller, Toffaleti, and Yang (sand). All methods except Meyer-Peter & Muller provide estimates of total load. Meyer-Peter & Muller estimates bed load only. For a complete listing of the limits of application for these methods as provided by HEC-RAS, see Appendix G.

The total load estimates from BORAMEP and Psands were compared directly with the HEC-RAS total load calculations for the five applicable methods. In 1992 geometry data was used for the HEC-RAS runs because the sediment data used in both BORAMEP and Psands was obtained around 1992. Estimating the incoming bed load for each reach was necessary before making comparisons with the Meyer-Peter & Muller bed load. The suspended load was estimated as the portion of the total load that was smaller than the d_{10} of the bed material samples collected at the San Acacia gauge for subreach 1 and at SO-lines for subreaches 2 and 3.

The total load for a discharge of 5000 cfs was determined from the rating curves developed from the BORAMEP and Psands results. The bed load was then determined by multiplying the total load by the percent of material considered to be wash load. The slope of the channel was varied until a slope was reached that matched incoming sediment supply and transport capacity. The equilibrium slope was determined for each method in each subreach.

7.3.2. Results

The total load rating curve for the incoming sand-sized sediment is shown in Figure 7.8. Table 7.9 shows the total load obtained from the regression curves at a discharge of 500 cfs, the average d_{10} of the bed material for each subreach, the percent of the suspended sediment that is smaller than the d_{10} of the bed material, and the bed load for each subreach.

Table 7.9 Total load and bed load calculations

	Total Load (tons/day)	Bed material d_{10} (mm)	% smaller than d_{10} of bed	Bed Load (tons/day)
Subreach 1	33298	0.0625	71.9	9344
Subreach 2	35460	0.125	82.3	6263
Subreach 3	38790	0.125	81.8	7068

Figure 7.8 Total load rating curves from BORAMEP and Psands

The equilibrium sediment transport capacity and slope are shown for each reach and each method in Table 7.10. Some of the methods did not approach the target transport capacity within a reasonable range of slopes. A reasonable range of slope is a condition where a slope is predicted. These reaches do not show a specific equilibrium slope or transport capacity.

Table 7.10 Equilibrium slope determined from transport capacity equations

Sediment Transport Equations	Transport Capacity (tons/day)	Slope	Transport Capacity (tons/day)	Slope	Transport Capacity (tons/day)	Slope
Ackers & White	-	<0.00009	31255	0.00015	-	<0.00009
Engelund & Hansen	33234	0.00052	35020	0.00062	38141	0.00009
Laursen	-	<0.00009	40306	0.00041	-	<0.00009
Meyer-Peter & Muller	-	>0.01	6913	0.01	5668	0.01
Toffaletti	32519	0.00047	29191	0.00052	39097	0.00021
Yang - Sand	31348	0.00041	36112	0.00072	-	<0.00009
Average Slope		0.00193		0.00207		0.0018
Median Slope		0.00044		0.00057		0.00009

Methods by Engelund & Hansen and Toffaleti were the only methods able to determine an equilibrium slope for all subreaches, while Laursen and Ackers & White were only able to determine an equilibrium slope for subreach 2. The methods that predicted equilibrium slopes closest to the current slope were Engelund & Hansen in subreach 1, Yang in subreach 2, and Toffaleti in subreach 3. Meyer-Peter & Muller estimated very high slopes for all reaches. This may be due to the large amount of bed material load typically transported as suspended load in this section of the river, leaving very little material to be transported as bed load. Based on their ability to predict reasonable slopes in all subreaches, Engelund & Hansen and Toffaleti seem to be the best methods for determining transport capacity in the Escondida reach.

The average equilibrium slopes predicted by the sediment transport methods are much higher than expected for all reaches due to the influence of the Meyer-Peter & Muller method. This occurred because the Meyer-Peter & Muller method is more applicable for coarser bed rivers. The median slopes, however, present a reasonable estimate of the equilibrium slopes for subreaches 1 and 2. The median slope estimated for subreach 3 is very low when compared to the other subreaches and the other methods used to predict the equilibrium slope. Based on the median slope estimates, the channel slope will decrease by 42% in subreach 1, 30% in subreach 2 and 88% in subreach 3. The decrease in slope correlates well with the aggradational trend seen recently in subreach 3, but does not correlate well with the degradational trend seen in subreaches 1 and 2.

7.4. SAM

7.4.1. Methods

HEC-RAS stable channel design program, known as SAM, was used to determine the equilibrium slope and width for a series of suspended sediment inputs. SAM was developed for use as a preliminary design tool for flood control channels. The program assumes a trapezoidal channel and steady uniform flow in calculations. Given suspended sediment and water discharges, as well as a bed material gradation, SAM computes combinations of stable depth, width, and slope for the channel using Copeland's flow resistance and sediment transport equations. The series of slope and width combinations can then be plotted. The minimum point on the resulting slope vs. width graph is the point of minimum stream power for the input conditions.

The 2002 channel properties were used for the SAM analysis. The inputs included a bank slope of 2H:1V, a bank roughness of $n=0.4$, a discharge of 5000 cfs, and bed material gradation of $d_{84} = 0.45$ mm, $d_{50}=0.3$ mm, $d_{16}=0.18$ mm. A series of suspended sediment concentrations between 800 mg/L and 4500 mg/L were input into SAM as well.

7.4.2. Results

Figure 7.9 shows the slope vs. width curves for each suspended sediment concentration. The width and slope of the channel for 2002 conditions are plotted for comparison. The width was determined from GIS platform measurements and the channel slope was determined from HEC-RAS. The point of minimum stream power on the graph predicts a width of about 150 ft regardless of the bed material concentration (HEC-RAS Manual). The predicted width is much less than the equilibrium width predicted by any other method.

Figure 7.9 Results from SAM for 2002 conditions at Q = 5000 cfs

Table 7.11 shows the width and slope for each subreach and the entire reach for the 2002 conditions. This width and slope are also plotted in Figure 7.9. Table 7.11 also shows the suspended sediment concentration at each location and the width and slope calculated by SAM for those suspended sediment concentrations. While the equilibrium width is much lower than other methods predict, the equilibrium slope is reasonable when compared with other methods.

Table 7.11 Current conditions and equilibrium slope and width from SAM

		Subreach 1	Subreach 2	Subreach 3	Total
2002	SS C (mg/L)	2629	3588	4547	3588
	Slope	0.00099	0.00093	0.00065	0.00091
	Width (ft)	334	436	265	381
SAM	Slope	0.000704	0.000878	0.001037	0.000878
	Width (ft)	163.5	155.9	153.3	155.9

8. Discussion

8.1. Historic trends and current conditions in the Escondida reach

Observed Channel Planform Change Over Time

Based on visual observations of the GIS non-vegetated active channel planforms, the channel planform has become straighter since 1918. This observation is confirmed by a steady decrease in sinuosity (see **Figure 3.6**). The decrease in sinuosity is larger in subreach 3 between 1918 and 1935 than the other reaches. The straightening was likely caused by flood control and irrigation efforts implemented during the 1920's and 1930's. At the same time, the upper portion of the channel transitioned from a braided, multi-thread channel to a much narrower, single thread channel.

The total channel has narrowed slightly between 1962 and 2002, with the greatest decrease in width occurring between 1985 and 1992 (see Figure 3.12). The decrease in top width is likely related to a corresponding increase in depth in the channel at the same time. It has been observed that during low flows this reach has low flow braids and at higher flows acts as an essentially straight single threaded channel.

Channel classification

The results of the channel classification methods indicated that the channel was primarily a straight or braided channel. The methods that most closely estimated the actual channel planform were those that indicated a straight planform, as braiding is only seen in localized areas of the channel during low flows. Leopold and Wolman, Schumm and Kahn, and Nanson and Croke all indicated a straight channel planform. Rosgen's method also provides a good description of the channel planform. Rosgen describes the channel as slightly to moderately entrenched with well-developed floodplains.

Vertical movement

Both aggradation and degradation were observed through changes in the mean bed elevation over time (see Figure 3.8 and Figure 3.9). Between 1962 and 1985, subreach 1 and subreach 2 showed 2 to 4 feet of aggradation, while subreach 3 showed about 4 feet of degradation. This trend was reversed between 1985 and 2002. The cyclical nature of the aggradation and degradation may be caused by complex response. Complex response results in several periods of aggradation and degradation in a reach due to a change in the system (Schumm 1979). The Escondida reach has been subjected to many changes, such as levee and dam construction and channelization. Any combination of these changes could have led to the complex response seen in the mean bed elevation.

The difference mass curve developed from suspended sediment gauge data also shows a cycle of aggradation and degradation. Aggradation was seen between

1960 and 1978. This was followed by about 5 years of degradation, then 6 years of aggradation. Finally, another cycle of degradation occurred from about 1992 until the end of the data in 1995. Continuing to analyze the difference mass curve as more data becomes available may give an indication as to when the channel is approaching equilibrium. As the channel approaches equilibrium, the oscillations between aggradation and degradation should become smaller.

Channel geometry

Table 8.1 shows the changes in each channel geometry parameter. A plus (+) indicates an increase, a minus (-) a decrease, and an equals (=) no change in the parameter value.

Table 8.1 Channel geometry changes

2	-	-	-	+	+	-	+	-
3	+	+	+	+	-	+	-	-
Total	+	+	+	-	+	+	-	-

Lateral movement

Significant channel migration occurred at numerous locations throughout the reach (see Table 3.5). Shifts in channel banks of more than 100 feet were not uncommon. The largest channel movements were seen between 1962 and 1972. The channel migration may be due to the placement of improvements such as

levees that both straighten the channel and restrict the locations where migration is possible between 1949 and 1962 primarily. The migration may also be a response to earlier channelization efforts.

Bed material

Sand-sized particles are the primary bed material throughout the reach. Historically, the bed material has ranged from very fine sand to medium sand. A slight coarsening of the bed material has been seen between 1972 and 2002 (See Figure 3.17). This may be due to the effects of dam installation and reduced sediment supply from upstream ephemeral tributaries. The coarsening may also be due to new inputs of coarse material from tributaries and arroyos, a decreased supply of fine sediments, or increased transport capacity due to higher discharges.

Discharge

The daily discharge at both the San Acacia and San Marcial gauges increased to about 4 times the previous daily discharge around 1979. The daily discharge decreased by about 3 times around 2000 (see Figure 4.1). These changes may have occurred due to the installation and operation of the Cochiti Dam as well as the operation of the San Acacia Diversion Dam.

Suspended sediment

The daily suspended sediment discharge recorded at both gauges has changed little since early 1960's (see Figure 4.2). As a result, the suspended sediment concentration has varied inversely with discharge over time. The concentration decreased by about 5 times following the increase in discharge in 1979. The effects of the recent decrease in discharge are not known because suspended sediment data is unavailable after 1996. Based on Table 4.2 the sediment load in tons/day is greater at San Marcial than at San Acacia. In the late 1950's the sediment load at San Marcial is 5 times greater than San Acacia. In the late 1960's the sediment load is still greater at San Marcial, however the magnitude is not as high.

Floodplain Inundation

Two locations in the lower portion of the reach have large, active floodplains. These floodplains typically become active at about 3000 cfs. The recurrence interval of a 3000 cfs flow indicates that the floodplain is inundated on about an annual basis. The floodplain became active between 1000 cfs and 2000 cfs before 1985 in the lowest section of the reach, indicating that the channel has entrenched since 1972.

Bedforms

Neither of the bedform predictors was able to adequately predict the bedforms observed in the Escondida reach. Upper regime anti-dunes and plane bedforms

were predicted correctly most often. The difficulty in calculating the expected bedforms stems from the high variability of the cross-sections in the reach. Two or more different types of bedforms were typically observed at a typical cross-section. Upper regime bedforms were easier to predict because the cross-section variability had less of an effect at the high flows necessary to produce upper regime bedforms.

8.2. Channel response models

8.2.1. Schumm's (1969) river metamorphosis model

Schumm (1969) developed a model to describe a channel's response to changes in water and sediment discharge. Schumm hypothesized that changes in water and sediment discharge would effect channel width, depth, width/depth ratio, channel slope, sinuosity and meander wavelength. The response of these parameters can be described by the following equations where a plus (+) exponent indicates an increase and a minus (-) exponent indicates a decrease.

Decreased bed material load:

$$Q_s^- \sim W^- D^+ P^+ L^- S^-$$

Increase bed material load:

$$Q_s^+ \sim W^+ D^- P^- L^+ S^+$$

Decreased water discharge:

$$Q^- \sim W^- D^- L^- S^+$$

Increased water discharge:

$$Q^+ \sim W^+ D^+ L^+ S^-$$

Decreased water discharge and bed material load:

$$Q^- Q_t^- \sim W^- D^\pm F^- L^- S^\pm P^+$$

Increased water discharge and bed material load:

$$Q^+ Q_t^+ \sim W^+ D^\pm F^+ L^+ S^\pm P^-$$

Where Q is water discharge, Q_s is bed material load, Q_t is the percent of the total load that is sand or bed material load, W is channel width, D is flow depth, F is width/depth ratio, L is meander wavelength, P is sinuosity, and S is channel slope.

Table 8.2 shows Schumm's equations in tabular form. In addition, Table 8.3 shows the observed changes in the Escondida reach for each year and subreach.

Table 8.2 Schumm's (1969) channel metamorphosis model

1985-1992					
1	-	+	-	-	-
2	+	+	-	+	+
3	-	+	+	-	-
Total	-	+	-	-	+
1992-2002					
1	=	-	+	+	-
2	+	-	-	+	-
3	+	-	+	+	+
Total	+	-	-	+	-
1962-2002					
1	+	-	-	+	-
2	-	+	=	-	-
3	+	+	+	+	+
Total	+	-	=	+	-

Comparing the observed changes in channel properties to Schumm's equations gives an indication of what the channel may be responding to. Schumm's model seems to work best in the Escondida reach between 1985 and 2002. Few of the changes in the earlier years match the model. The model indicates that between 1985 and 1992, the channel was likely responding to a decrease in discharge and sediment load. This observation is opposite to the changes in discharge and

sediment load observed at the San Acacia and San Marcial gauges at the same time. In addition, the model indicates that between 1992 and 2002, the channel was responding to an increase in both discharge and sediment load. An increase in sediment load was observed during this time, but an increase in discharge was not. This may indicate that the channel is responding more to the changes in sediment supply than to changes in discharge.

8.2.2. Lane's (1955) balance

Lane's (1955) balance model is illustrated in Figure 8.1. The channel parameters examined by Lane were channel slope, discharge, median grain size, and sediment discharge. The model states that a change in any of the four driving variables will result in a change of the other three variables such that the channel will tend toward a new equilibrium state.

Figure 8.1 Lane's balance(1955)

Table 8.4 shows the observed channel changes from 1962 to 2002 as well as the variable to which the channel may be reacting. The variable initiating change was determined by selecting a variable as the initial point of change, and evaluating the changes in the other variables to determine if they followed the pattern outlined by Lane. If the changes balanced according to Lane, the variable could have been the trigger of channel change. Discharge and suspended sediment discharge were always considered first because the channel cannot change the amount of water or sediment entering the reach from upstream. Suspended sediment data was not available after 1996, so the

change from 1992 to 2002 is unknown. The suspended sediment discharge for the unknown time was assumed to be constant for the purpose of this analysis.

Table 8.4 Observed Changes in Lane Balance Parameters and the Corresponding Trigger Variable

Subreach	Q	S	Q _s	d ₅₀	Trigger variable
1962-1972					
1	=	-	+	-	d ₅₀
2	=	+	+	-	Q _s
3	=	+	+	-	Q _s
Total	=	+	+	-	Q _s
1972-1985					
1	+	-	+	+	Q
2	+	+	+	+	None
3	+	-	+	-	None
Total	+	=	+	+	None
1985-1992					
1	=	-	=	+	None
2	=	-	=	+	None
3	=	+	+	+	S or d ₅₀
Total	=	-	=	+	None
1992-2002					
1	-	+		+	None
2	-	-		+	d ₅₀
3	-	+		-	Q
Total	-	-		+	d ₅₀

According to Lane's balance, between 1962 and 1972, the channel was primarily reacting to a change in the incoming suspended sediment discharge because d₅₀ did not change much. Between 1985 and 1992, the channel did not change in a way that was predicted by Lane. Assuming a relatively constant suspended sediment discharge, the channel seemed to be reacting to an increase in median grain diameter. It is likely that the channel is actually under the influence of multiple channel changes at any given time. However, this simplified approach gives some idea of what changes may be having the greatest influence on the channel morphology.

8.3. Potential future equilibrium conditions

8.3.1. Equilibrium Width

Hydraulic Geometry

The hydraulic geometry equation developed by Blench (1957) gave equilibrium widths that most closely matched the current channel conditions. However, Blench may not be the best method for predicting equilibrium width because the channel was likely not in equilibrium between 1962 and 2002. Simons and Albertson (1963), Nouh (1988), Lacey (from Wargadalam 1993), and Julien-Waradalam (1995) all predicted similar equilibrium widths between 200 ft and

300 ft. The consistent prediction by these four methods indicates that they may be the most effective in predicting equilibrium width.

Hyperbolic and Exponential Models

The hyperbolic model developed by Williams and Wolman (1984) fit well with historic width data from the Escondida reach. The widths predicted by the hyperbolic model ranged from about 300 ft to about 450 ft. The method predicted a negative equilibrium width for subreach 1, but predicted a reasonable width for 2020. More data should be added to the model to improve the equilibrium prediction for subreach 1.

The exponential model developed by Richard et al. (2005) produced results very similar to those calculated by the hyperbolic model. However, this model was able to predict reasonable equilibrium widths for all subreaches and the total reach.

SAM

The final equilibrium width prediction method used was the HEC-RAS stable channel design program (SAM). Based on the incoming suspended sediment concentration estimated for each subreach and the total reach, the equilibrium widths for the channel were all about 160 ft. This width is less than the widths predicted by the other methods, but it still provides a reasonable estimate of equilibrium channel width.

8.3.2. Equilibrium Slope

Hydraulic Geometry

Julien and Wargadalam (1995) predicted equilibrium slopes for the 2002 channel geometry between 0.00083 and 0.00139. These slopes are much steeper than the slopes observed in the channel during that time, indicating that the channel may not be in equilibrium. The predicted slopes are, however, reasonable when compared to historic channel slopes.

SAM

The equilibrium slope was also estimated from the HEC-RAS stable channel design program. The program estimated the equilibrium slope to be between 0.00065 and 0.00099 depending upon the incoming suspended sediment concentration. These results are very similar to the predictions made by Julien-Wargadalam.

Sediment Transport

The HEC-RAS sediment transport analysis was used to determine an equilibrium slope for the channel based on sediment transport. The equilibrium slope was estimated as the slope at which sediment supply equals sediment transport capacity. Engelund & Hansen and Toffaleti were the only methods able to provide reasonable slope predictions for all subreaches. These methods estimated the equilibrium slope to be between 0.00009 and 0.00062. This slope

range is much less steep than the slopes estimated by Julien-Wargadalam and SAM. The slopes are also much less steep than the historic slopes in the reach. This method may not be the best for predicting equilibrium slope for this reach. A better accounting of incoming sediment from all sources, such as arroyos and other ungauged tributaries may improve the predictions provided by the sediment transport analysis.

9. Summary

The Escondida reach was analyzed for this study. The reach covers 17.7 miles of the Middle Rio Grande in central New Mexico. Important changes occurring in the Escondida reach between 1918 and 2005 were analyzed using a number of techniques. Changes in channel geometry and morphology, and water and sediment discharge were observed. In addition, historic bedform data were analyzed. Finally, the equilibrium conditions of the reach were estimated.

Spatial and temporal trends in channel geometry and morphology were identified using visual observations of aerial photographs and GIS active channel planforms, cross-section surveys, hydraulic modeling using HEC-RAS, and channel classification methods. Observations of the GIS active channel planforms and aerial photographs show that the channel has narrowed between 1918 and 2005. The most significant narrowing has occurred in the upper portion of the reach. Analysis of channel geometry trends using HEC-RAS hydraulic modeling output shows a series of increases and decreases in most channel properties. The fluctuations in channel geometry may be the result of a complex response to past channel changes. Bed material samples obtained from cross-section surveys and at the San Acacia and San Marcial gauges between 1962 and 2002 show a slight coarsening of the bed from a mean diameter of 0.15 mm to 0.31 mm.

Historic bedform observations were compiled and compared to predicted bedforms at the survey locations. Simons and Richardson and van Rijn were used to calculate the expected bedforms at each survey locations. These predictions were compared with field observations of bedforms. The bedform predictor methods produced adequate results. Large scatter was observed in the data, especially in the prediction of lower regime bedforms. This scatter is likely due to the wide variability across individual cross-sections in the reach.

Trends in water and sediment discharge were analyzed using mass curves developed from USGS gauge data. The mass curves show a wet period between 1979 and 2000. This increase in discharge was also observed in upstream reaches. The increase in discharge caused the Escondida reach to carry a similar magnitude of discharge as the upstream reaches, where, historically, the reach carried much lower discharges. The daily mean suspended sediment discharge remained nearly constant for the entire period of record. The difference mass curve shows periods of aggradation and degradation that approximately correlate with changes in mean bed elevation.

Estimates of potential equilibrium slope and width conditions were made using hydraulic geometry equations, hyperbolic and exponential regressions, stable channel geometry, and sediment transport relationships. An equilibrium width of around 300 ft was estimated by several methods, indicating that this is a reasonable estimate of the future channel width. Julien-Wargadalam and SAM

predicted equilibrium slopes between 0.00065 and 0.00139, depending on the subreach and the method used. These slopes are within a reasonable range of the current slope and provide a good estimate of the direction of potential slope change in each subreach since the reach currently has a slope of 0.0008.

The main conclusions of this study are:

- The active channel has narrowed and the sinuosity decreased from 1.19 to 1.09 between 1918 and 2005. In addition, the mean bed material diameter increased from 0.15 mm to 0.31 mm between 1962 and 2002.
- Bedform prediction methods by van Rijn and Simons and Richardson produced a reasonable fit to the observed bedform data. The data showed wide scatter, likely caused by the high degree of variability across a cross-section.
- The water discharge indicated a period of increased water discharge between 1979 and 2000. The increase in discharge that occurred in 1979 was observed in upstream reaches, but was more dramatic in the Escondida reach.
- Equilibrium width and slope predictors forecast a channel width of about 300 ft and a slope between 0.00065 and 0.00139. These estimates were confirmed by multiple methods and seem to be reasonable estimates.

The collective observations of the reach indicate that this is a very dynamic reach that has not yet reached an equilibrium state. The channel will likely continue to narrow. Lateral movement and sinuosity changes are also likely as the channel attempts to reach an equilibrium slope.

Appendix B – Aerial Photography Information

Table B.1 Aerial photography survey dates and information

Date	Mean Daily Discharge		Scale	Notes (1918-2002:from Novak 2006 2005: from ArcGIS metadata)
	San Acacia	San Marcial		
1918	No Data	No Data	1:12,000	Hand-drafted linens (39 sheets). USBR Albuquerque Area Office. Surveyed in 1918. Published in 1922.
1935	No Data	No Data	1:8,00	Black and white photography. USBR Albuquerque Area Office. Flown in 1935. Published in 1936.
1949	No Data	No Data	1:5,000	Photo-mosaic. J-Ammann Photogrammetric Engineers, San Antonio, TX. USBR Albuquerque Area Office.
March 1962	25 cfs	0 cfs	1:4,800	Photo-mosaic. Abram Aerial Survey Corp, Lansing, MI. USBR Albuquerque Area Office.
April 1972	4 cfs	0 cfs	1:4,800	Photo-mosaic. Limbaugh Engineers, Inc., Albuquerque, NM. USBR Albuquerque Area Office.
March 1985	1900 cfs	1320 cfs	1:4,800	Orthophoto. M&I Consulting Engineers, Fort Collins, CO. Aero-Metric Engineering, Sheboygan, MN. USBR Albuquerque Area Office.
February 1992	1020 cfs	630 cfs	1:4,800	Ratio-rectified photo-mosaic. Koogle and Poules Engineering, Albuquerque, NM. USBR Albuquerque Area Office.
February 2001	770 cfs	560 cfs	1:4,800	Ratio-rectified photo-mosaic. Pacific Western Technologies, Ltd., Albuquerque, NM. USBR Albuquerque Area Office.
March 2002	310 cfs	150 cfs	1:4,800	Digital ortho-imagery. Pacific Western Technologies, Ltd., Albuquerque, NM. USBR Albuquerque Area Office.
April 2005	2270 cfs	1680 cfs	1:4,800	Digital ortho-rectified imagery. Aero-Metric, Inc., Fort Collins, Co. USBR Albuquerque Area Office.

Appendix C – HEC-RAS Model Output

1962

1972

1985

1992

2002

Table C.1 HEC-RAS output for 1962 geometry

HEC-RAS Plan: 1962(8-7-06) River: Middle Rio Grande Reach: Socorro Profile: PF 1

Appendix G – HEC-RAS Sediment Transport Application Limits

The information presented in the pages below was taken from HEC-RAS v. 3.1.3 (USACE 2005).

Ackers-White (flume):

$0.04 < d < 7 \text{ mm}$ $1.0 < s < 2.7$
 $0.07 < V < 7.1 \text{ fps}$ $0.01 < D < 1.4 \text{ ft}$
 $0.00006 < S < 0.037$ $0.23 < W < 4.0 \text{ ft}$
 $46 < T < 89 \text{ degrees F}$

A total load function developed under the assumption that fine sediment transport is best related to the turbulent fluctuations in the water column and coarse sediment transport is best related to the net grain shear with the mean velocity used as the representative variable. The transport function was developed in terms of particle size, mobility and transport. A dimensionless size parameter is used to distinguish between the fine, transitional, and coarse sediment sizes. Under typical conditions, fine sediments are silts less than 0.04 mm, and coarse sediments are sands greater than 2.5 mm. Since the relationships developed by Ackers-White are applicable only to non-cohesive sands, greater than 0.04 mm, only transitional and coarse sediments apply. Experiments were conducted with coarse grains up to 4 mm. This function is based on over 1000 flume experiments using uniform or near-uniform sediments with flume depths of up to 1.4 m. A range of bed configurations was used, including plane, rippled, and dune forms, however the equations do not apply to upper phase transport (e.g. anti-dunes) with Froude numbers in excess of 0.8. A hiding adjustment factor was developed for the Ackers-White method by Profitt and Sutherland (1983), and is included in RAS as an option. The hiding factor is an adjustment to include the effects of a masking of the fluid properties felt by smaller particles due to shielding by larger particles. This is typically a factor when the gradation has a relatively large range of particle sizes and would tend to reduce the rate of sediment transport in the smaller grade classes.

Engelund-Hansen (flume):

$0.19 < d_m < 0.93 \text{ mm}$ $0.65 < V < 6.34$
 $0.19 < D < 1.33 \text{ fps}$ $0.000055 < S < 0.019 \text{ ft}$
 $45 < T < 93 \text{ degrees F}$

A total load predictor, which gives adequate results for sandy rivers with substantial suspended load. It is based on flume data with sediment sizes between 0.19 and 0.93 mm. It has been extensively tested, and found to be fairly consistent with field data.

Laursen (Copeland) (field):

$0.08 < d_m < 0.7 \text{ mm}$ $0.068 < V < 7.8 \text{ fps}$
 $0.67 < D < 54 \text{ ft}$ $0.0000021 < S < 0.0018$
 $63 < W < 3640 \text{ ft}$ $32 < T < 93 \text{ degrees F}$

Laursen (Copeland) (flume):

$0.011 < d_m < 29 \text{ mm}$ $0.7 < V < 9.4 \text{ fps}$
 $0.03 < D < 3.6 \text{ ft}$ $0.00025 < S < 0.025$
 $0.25 < W < 6.6 \text{ ft}$ $46 < T < 83 \text{ degrees F}$

A total sediment load predictor, derived from a combination of qualitative analysis, original experiments and supplementary data. Transport of sediments is primarily defined based on the hydraulic characteristics of mean channel velocity, depth of flow and energy gradient, and on the sediment characteristics of gradation and fall velocity. Contributions by Copeland (Copeland, 1989) extend the range of applicability to gravel-sized sediments. The overall range of applicability is 0.011 to 29 mm.

MPM. Meyer-Peter Muller (flume):

$0.4 < d < 29 \text{ mm}$ $1.25 < s < 4.0$
 $1.2 < V < 9.4 \text{ fps}$ $0.03 < D < 3.9 \text{ ft}$
 $0.0004 < S < 0.02$ $0.5 < W < 6.6 \text{ ft}$

BED LOAD ONLY! A bed load transport function based primarily on experimental data. It has been extensively tested and used for rivers with relatively coarse sediment. The transport rate is proportional to the difference between the mean shear stress acting on the grain and the critical shear stress. Applicable particle sizes range from 0.4 to 29 mm with a sediment specific gravity range of 1.25 to in excess of 4.0. This method can be used for well-graded sediments and flow conditions that produce other-than-plane bed forms. The Darcy-Weisbach friction factor is used to define bed resistance. Results may be questionable near the threshold of incipient motion for sand bed channels as demonstrated by Amin and Murphy (1981).

Toffaleti (field):

$0.062 < d < 4 \text{ mm}$ $0.095 < d_m < 0.76 \text{ mm}$
 $0.7 < V < 7.8 \text{ fps}$ $0.07 < R < 56.7 \text{ ft}$
 $0.000002 < S < 0.0011$ $63 < W < 3640 \text{ ft}$
 $40 < T < 93 \text{ degrees F}$

Toffaleti (flume):

$0.062 < d < 4 \text{ mm}$ $0.45 < d_m < 0.91 \text{ mm}$
 $0.7 < V < 6.3 \text{ fps}$ $0.07 < R < 1.1 \text{ ft}$
 $0.00014 < S < 0.019$ $0.8 < W < 8 \text{ ft}$
 $32 < T < 94 \text{ degrees F}$

A modified-Einstein total load function that breaks the suspended load distribution into vertical zones, replicating two-dimensional sediment movement. Four zones are used to define the sediment distribution. They are the upper zone, the middle zone, the lower zone and the bed zone. Sediment transport is calculated independently for each zone and the summed to arrive at total sediment transport. This method was developed using an exhaustive collection of both flume and field data. The flume experiments used sediment particles with mean diameters ranging from 0.45 to 0.91 mm, however successful applications of the Toffaleti method suggests that mean particle diameters as low as 0.095 mm are acceptable.

Yang (field, sand):

$0.15 < d < 1.7 \text{ mm}$ $0.8 < V < 6.4 \text{ fps}$
 $0.04 < D < 50 \text{ ft}$ $0.000043 < S < 0.028$
 $0.44 < W < 1750$ $32 < T < 94 \text{ degrees F}$

A total load function developed under the premise that unit stream power is the dominant factor in the determination of total sediment concentration. The research is supported by data obtained in both flume experiments and field data under a wide range conditions found in alluvial channels. Principally, the sediment size range is between 0.062 and 7.0 mm with total sediment concentration ranging from 10 ppm to 585,000 ppm. Yang (1984) expanded the applicability of his function to include gravel-sized sediments.
