Abstract. For many years researchers have envisioned the development of compact high repetition rate tabletop soft X-ray lasers that could be routinely used in application in numerous disciplines. With demonstrated average powers of several mW and millijoule-level pulse energy at 46.9 nm, the Ne-like Ar capillary discharge-pumped laser is the first compact laser to reach this goal. In this paper we summarize the development status of high repetition rate tabletop soft X-ray lasers based on capillary discharge excitation, and give examples of their successful use in several applications. Results of the use of a capillary discharge pumped 46.9 nm laser in dense plasma interferometry, soft X-ray reflectometry for the determination of optical constants, characterization of diffraction gratings, laser ablation of materials, and plasma generation are described. The observation of lasing at 52.9 nm line in Ne-like Cl with output pulse energy up to 10 µJ is also reported.

1. Introduction

Capillary discharge excitation of Ne-like Ar plasmas has generated mW average powers of coherent soft X-ray radiation and millijoule-level pulses in a tabletop set up [1,2]. Multi-Hertz repetition rate operation generated an average power of ≈3.5 mW at a wavelength of 46.9 nm [2]. The advanced degree of development of this laser is summarized in the next section. There is also significant interest in extending the availability of practical discharge-pumped short wavelength lasers to other wavelengths. In Section 3 we discuss the generation of laser pulses at 52.9 nm (23.4 eV) in the 3p-3s J=0-1 line of Ne-like Cl. Section 4 summarizes the results of several recent experiments that demonstrate for the first time the use of a tabletop soft X-ray laser in several diverse areas of science and technology. These areas include; plasma physics, materials characterization and processing, and the characterization of soft X-ray optics.

2. Development status of the 46.9 nm Ne-like Ar tabletop laser: demonstration of milliwatt average power and millijoule-level pulses

The Ne-like Ar capillary discharge laser is perhaps the most mature tabletop soft X-ray laser developed to date. Table 1 summarizes the characteristics of this laser and its present output parameters. These laser output parameters were obtained utilizing aluminum oxide capillary channels 3.2 mm in diameter filled

*Permanent address: FCEyN, UBA, Argentina.
with preionized Ar gas at an optimized pressure of ~460 mTorr. The plasma columns were excited by current pulses of ~26 kA peak amplitude with a 10% to 90% rise time of approximately 40 ns. Figure 1 illustrates the size of the capillary discharge Ne-like Ar laser. This capillary discharge-pumped laser occupies a table space of approximately 0.4 m x 1 m, a size comparable to that of many widely utilized visible or ultraviolet gas lasers.

Figure 1. Photograph of capillary discharge soft x-ray laser (right) and applications chamber (left). A multimeter is shown in front of the laser to provide size reference.

In this laser the excitation current pulse is produced by discharging a water capacitor through a spark gap switch connected in series with the capillary load. The laser average output pulse energy was measured to increase from 0.075 mJ for a plasma column 16 cm in length, to 0.88 mJ for the plasma column 34.5 cm in length. At the output of the longest capillary the laser beam intensity approaches 1 GW/cm², and exceeds the saturation intensity by more than an order of magnitude.

Figure 2. Measured output pulse energy and average power of a table-top capillary discharge 46.9-nm laser operating at a repetition frequency of 4 Hz. (a) Shot-to-shot laser output energy and average output power compared to a walking average of 60 continuous laser pulses. (b) Distribution of the output pulse energy. Average pulse energy is 0.88 mJ and the standard deviation is 0.06 mJ.

Figure 2a shows the shot to shot variations of the measured laser output pulse energy and corresponding laser average power for a 34.5 cm long discharge operated at 4 Hz repetition rate. The average laser output power is about 3.5 mW, corresponding to ~8 x 10¹⁶ photons per second [2]. Figure 2b shows the average laser output energy per pulse is 0.88 mJ and that the energy of the highest energy pulses exceeds 1 mJ. More than 5000 laser shots were obtained from a single capillary. The full width at half maximum of the corresponding laser pulse is 1.5 ± 0.05 ns, longer than the 1.2 ns pulsewidth that we measured for an 18.2 cm long amplifier [3]. The average peak laser output power obtained with the longest plasma column is ±0.6 MW. The output beam intensity distribution has an annular shape. The peak to peak divergence was measured to be about 4.6 mrad for all capillary lengths between 18 and 34.5 cm. Recent measurements of the spatial coherence indicate that full spatial coherence is approached with the longest capillaries and that the peak spectral brightness is about 2 x 10²⁵ photonsm⁻² s⁻¹ r.m.s. bandwidth [4]. This value makes this table-top laser one of the brightest soft x-ray sources available.

3. Demonstration at 52.9 nm

There is also significant interest in short wavelength lasers to different disciplines and photophysics can significantly contribute. We have demonstrated the generation of Ne-like Cl utilizing a very coherent beam previously observed by Y. Li et al. [8] and the laser pulses produced by the pump laser in the 18.2 cm long discharge-pumped amplifier, 100 ns after the amplified spontaneous emission pulse, allowing for the generation of a pulse duration of up to 10 µs were measured operationally. The gain media was generated by a gas-pressure channel filled with pre-ionized carbon dioxide similar to that previously used to have been observed at Cl₂ pressures of 40 Torr. The current pulses of approximately 400 A were used in this discharge, the fast current pulse produced inversion in the 3p² ³S₂⁻ ground state.

Figure 3. On-axis emission spectrum of the J=0-1 laser line of Ne-like Cl₂. The J=0-1 laser line at 52.9 nm wavelength is much smaller than that of several neighboring transitions. The emission at 52.9 nm wavelengths was monitored using a vacuum photodiode.
3. Demonstration at 52.9 nm capillary discharge laser in Ne-like Cl

There is also significant interest in extending the availability of practical saturated laser ablation tabletop short wavelength lasers to different regions of the spectrum. In particular, applications in photochemistry and photophysics can significantly benefit from repetitive laser sources of high energy photon that are capable of causing single-photon ionization of neutral species, yet fall short of the 24.6 eV threshold for the photoionization of He. These applications include the study of nanoclusters created by optical, a technique that uses He as a carrier gas [5].

We have demonstrated the generation of laser pulses at 52.9 nm (23.4 eV) in the 3pS0-3sP1 transition of Ne-like Cl utilizing a very compact capillary discharge [6]. Laser amplification of this line was previously observed by Y. Li et al. in a plasma generated by exciting a solid KCl target with 450±20 J laser pulses produced by the powerful Asterix iodine laser facility at a rate of several shots per hour [7].

In the 18.2 cm long discharge-pumped plasma column used in the tabletop experiments reported herein, the amplified spontaneous emission intensity reached values of the order of the saturation intensity, allowing for the generation of a significantly greater laser output pulse energy. Laser pulses with energy up to 10 µJ were measured operating the discharge at repetition rates between 0.5 and 1 Hz.

The gain media was generated by rapidly exciting a 3.2 mm inside diameter aluminum oxide capillary channel filled with pre-ionized chlorine gas with a fast current pulse. The capillary discharge set up was similar to that previously used to obtain lasing in Ne-like Ar at high repetition rates [3]. Amplification was observed at Cl2 pressures ranging from 180 to 300 mTorr. The plasma columns were excited by current pulses of approximately 23 kA peak amplitude and 10-90 % rise-time of approximately 25 ns. In this discharge, the fast current pulse rapidly compresses the plasma creating a small diameter column [8,9] in which monopole collisional electron excitation of Ne-like Cl ions creates a large population inversion between the 3p S0 and 3s P1 levels, resulting in strong amplification at 52.9 nm.

Figure 3: On-axis emission spectra of the Cl capillary discharge plasma in the region between 30 and 70 nm.
(a) Spectrum corresponding to a 120 mTorr discharge. (b) Spectrum corresponding to a 224 mTorr discharge. In the latter, the dominance of the 59.2 nm Ne-like Cl transition is a clear indication of strong amplification.

Figure 3 shows spectra of the axial emission of the discharge, covering a 40 nm region in the vicinity of the J=0-1 laser line of Ne-like Cl. The spectrum obtained at a pressure of 120 mTorr (Fig. 3a), shows line emission at the 52.9 nm wavelength of the laser transition. However, the intensity of this line is weak, smaller than that of several neighboring transitions of Cl VI and Cl VII, which cannot be inverted. In contrast, at 224 mTorr, the optimum pressure for lasing (Fig. 3b), the laser line is over two orders of magnitude more intense and completely dominates the entire spectrum. This is clear evidence of large amplification in the 52.9 nm line. The energy and temporal evolution of the laser output pulse were monitored with a vacuum photodiode.
intensity of the incident beam was measured by scanning the angle of 1 Hz.

4.2.1. Determination of optical constants

The optical constants for Si, GaP, and InP are obtained by fitting the measured data for a 2.7 mm long sample of InP with a 100 orientation, cut from a bulk material. The results, obtained from normal incidence where the reflection is the same as the incident laser, are shown in figure 6. The measurements on the sample were made in steps of 5 mm. The results show that the optical constants for the bulk material are different from those of the untreated surface. This suggests that the surface treatment has a significant effect on the optical properties of the InP.

4.2. XUV Reflectometry

We took advantage of the high repetition rate of the laser to conduct reflectivity measurements as a function of angle. These measurements resulted in the determination of optical constants at 46.9 nm for several materials, and in the characterization of XUV multilayer mirrors. The experimental setup used to perform soft X-ray reflectometry is shown in figure 5. The measurements were conducted in a vacuum chamber placed at about 1.5 m from the exit of the Ne-like Ar signal laser. The samples were mounted on the axis of a rotation stage driven by a stepping motor, which allowed for the selection of angles of incidence between 0 and 90 degrees. The intensity of the reflected beam was recorded with a vacuum photodiode (labeled "A" in fig. 5), that was mounted on a lever arm that followed the angular motion of the reflected beam. To overcome scattering of the data due to shot to shot intensity variations of the laser, the intensity of the reflected beam was normalized by the
en

ticiently of those of electron diffusively. The intensity of the incident beam for each laser pulse. The angular dependence of the reflectivity was measured by scanning the angle of incidence while repetitively firing the laser at a repetition frequency of 1 Hz.

Figure 5. Schematic diagram of the laser reflectometer used in the measurement of XUV optical constants of materials.

4.2.1. Determination of optical constants of materials

The optical constants for Si, GaP, InP, GaAs, GaAsP and Ir at a wavelength of 46.9 nm (26.5 eV) were obtained by fitting the measured angular dependence of the reflectivity with the Fresnel formula. Figure 6 is an example of the reflectance data obtained as a function of incident angle for a bulk crystalline sample of InP with a 100 orientation, consisting of 300 contiguous laser pulses for a 90 degree rotation of the sample. The results, obtained from the fits of the experimental data, are summarized in Table 2. The high intensity of the laser source is an advantage for the accurate measurement of the reflectivity at near normal incidence where the reflectivity of most materials is low. Our analysis of the data made use of models that take into account the presence of a surface layer of contamination, which develops on most materials in a natural atmospheric environment. In order to characterize the influence of the surface layer on the measurement, the samples were chemically treated in a 5% solution of HF in distilled water for approximately 5 min and were then rinsed with acetone and methanol. Measurements of the treated and untreated samples that had different surface layer characteristics gave similar optical constants for the bulk material. This suggests that the approach used in this work is capable of yielding reliable values of the optical constants for the bulk material in the presence of surface layer contaminants. The measurements of the optical constants of InP and GaAsP constitute the first experimental values at this wavelength, while for the rest of the materials the values obtained for the other samples are in most cases

Figure 6. Measured and calculated reflectivity for 100 crystalline InP as a function of incident angle \( \theta \). (a) Before chemical treatment. The dotted curve corresponds to \( n = 0.92 + i \cdot 0.14 \) without the surface layer, the solid curve considering a surface layer: \( n = 0.88 + i \cdot 0.087 \) (layer: \( n = 0.82 + i \cdot 0.39 \), thickness \( d = 1.8 \text{nm} \)). (b) After chemical treatment. The dotted curve corresponds to: \( n = 0.91 + i \cdot 0.13 \) without the surface layer, the solid curve considering a surface layer: \( n = 0.88 + i \cdot 0.09 \) (layer: \( n = 0.84 + i \cdot 0.26 \), thickness \( d = 2.5 \text{nm} \)).
in good agreement with tabulated values. These measurements and the analysis of the data are discussed in more detail in the paper by I. Artioukov in [14,15].

4.2.2. Angular dependent reflectivity of Si/Sc multilayer mirror

Utilizing the reflectometer described above, measurements were made of the angular dependent reflectivity of Si/Sc multi-layer mirrors designed for use at 46.9 nm. The multilayer coatings were deposited on super-polished borosilicate substrates by dc magnetron sputtering with a period of 18-27 nm and a ratio of layer thickness H(Sc)/H(Si)=0.786 [17]. As an example, figure 7 shows the measured reflectivity as a function of incidence angle for a mirror designed to operate at normal incidence. The graph corresponds to the average of four runs. The runs varied in the number of data points collected from 200 to 400 for a scan angle of 90 degrees. A near normal incidence reflectivity of 43% was measured at 1.6 degrees.

![Reflectivity vs. Incidence Angle](image)

Figure 7. Measured reflectivity of a Si/Sc multilayer mirror at 46.9 nm as a function of incidence angle.

4.3. Generation of a polarized soft x-ray beam and application to the characterization of diffraction gratings

We have also demonstrated the generation of a highly polarized soft x-ray beam. The radiation emitted by a high average power discharge pumped tabletop Ne-like Ar soft x-ray laser operating at 46.9 nm was polarized using a pair of Si/Sc multilayer mirrors designed for 45 degree operation. A degree of polarization greater than 0.96 was obtained. These results are discussed in more detail in these proceedings in the paper by Vinogradov et al. [18], and in a recent paper by Benware et al [19]. Polarized and unpolarized laser beams passed through an amorphous germanium (Ge) solid immersion lens. This setup was used to perform high throughput experiments with high accuracy without requiring the use of a high power laser. The Ge-Si superlattice material was used in the experiments instead of a Ge lens because it is a better material for the application. The Ge-Si superlattice material was used in the experiments instead of a Ge lens because it is a better material for the application. The Ge-Si superlattice material was used in the experiments instead of a Ge lens because it is a better material for the application.
and unpolarized laser beams produced by this tabletop laser were used to characterize the efficiency of a diffraction grating. The efficiencies for different diffraction orders were measured as a function of angle of incidence and compared with the results of model simulations. This measurement technique provides valuable benchmarks to improve electromagnetic codes used in the design of soft x-ray diffraction gratings, and illustrate the potential of compact tabletop soft x-ray lasers as a new tool for the characterization of short wavelength optics at the manufacturer’s site. In this proceedings we do not have sufficient space to give a complete report on these results, and they will be published elsewhere in the near future.

4.4. Soft x-ray laser ablation

Focused soft x-ray laser beams have the potential to reach very high intensities and energy densities, opening new applications for short wavelength coherent radiation. Preliminary results of an attempt to focus laser pulses from a collisional soft x-ray laser pumped by a large optical laser have been reported [20]. Here we summarize the characterization of a focused 46.9 nm laser beam generated by a Ne-like Ar capillary discharge soft x-ray laser, and the results of the first laser ablation experiment with a soft x-ray laser. The experimental setup used to focus the laser beam and characterize its intensity distribution in the focal region is shown in figure 8.

![Experimental setup used to focus the soft x-ray laser beam.](image)

The soft x-ray laser pulses had an energy of about 0.13 mJ and 1.2 ns FWHM duration and were generated at a repetition rate of 1 Hz by amplification in a 18.2 cm long Ar capillary plasma. The laser beam was focused by a spherical (R=10 cm) Si/Sc multilayer-coated mirror of ≈40 % normal incidence reflectivity located in a vacuum chamber at 256 cm from the exit of the capillary amplifier. The mirror was positioned at normal incidence with the purpose of minimizing aberrations and the reflected beam was focused on axis, where it impinged on the flat face of a target consisting of a thin (2 mm thick) metal strip. The focused laser beam was observed to have sufficient intensity to ablate aluminum, stainless steel and brass when the samples are positioned within several hundred μm from the focus. The characteristics of the imprints on the metal surface depend not only on the intensity distribution, but also on the melting point and heat conductivity of the sample, and on the duration of the laser pulse [21]. Nevertheless, they can give useful two-dimensional information of the focused laser beam intensity distribution. To map the evolution of the laser intensity distribution along the propagation axis we mounted the target on a translation stage driven by a computer controlled stepper motor. The axis of motion of the translation stage was positioned at an angle with respect to the optical axis. Series of imprints of the beam for positions along the optical axis were obtained by continuously moving the translation stage while repetitively firing the laser at a repetition rate of 1 Hz.

Figure 9 is a scanning electron microscope (SEM) photograph of the surface of a brass target showing the progression of ablation patterns obtained as the target was moved away from the mirror and towards the
focus. Each ablation pattern is the result of a single laser shot. At an axial distance of a few hundred μm from the focal region, the ablation patterns have the shape of thin annular disks. These rings show good azimuthal symmetry, except for a small discontinuity where the incoming beam was blocked by the target. As the focal region is approached, the thickness of the ablated rings increases, and a central spot develops. The depth of the rings was measured to be ~2 μm. Finally, very near the focus, the patterns evolve into a single spot with a deep hole on axis. The smallest spot has an outer diameter of about 17 μm and contains a deep central hole of about 2-3 μm diameter.

To increase the understanding of the characteristics of the laser beam in the focal region and to obtain an estimate of the power density deposited, we analyzed these results with ray-tracing computations. Figure 10 shows the computed radial cross section of the beam intensity distributions in the focal region. For comparison with the experiment, the measured boundaries of the ablated regions are represented as black dots in the same figure. All the major features of the observed ablation profiles of figure 9 are well described by the ray tracing computations.

The computations show that at a few hundred μm from the focal region, the highest concentration of rays defines a thin ring. Also, in accordance with the experiment, a central peak is observed to develop as the focal region is approached. Both features are the result of the spherical aberration that causes the rays to converge and cross at those locations. Similarly, the spherical aberration causes the central peak, which begins to develop when the outermost rays converge on the axis. Near the so-called “plane of minimum confusion” the intensity distribution is responsible for the deep central diameter region is estimated to intersect this region. The analysis is dominantly limited by the spherical aberration.

4.5. Plasma generation with a focus

The successful demonstration of the effects shown in the previous section opens the possibility of controlling plasma characteristics. The fact that the focus is capable of inducing single plasma mechanisms of these plasmas from the interaction of the plasma generated with the focused beam.

Focusing of the beam of the 46.9 nm, multilayer coated mirror (R=100%) was used in the experiment. For excitation of carbon, aluminum, and silicon, the results clearly demonstrate the feasibility of using a focused radiation. Future work will include emission of other elements and the use of different mirror coatings.
4.5. Plasma generation with a focused soft x-ray laser beam

The successful demonstration of focusing of a soft x-ray laser beam to the large intensities mentioned in the previous section opens the possibility of generating and studying dense plasmas of unique characteristics. The fact that the critical density for 46.9 nm laser radiation is \(5 \times 10^{23} \text{ cm}^{-3}\) and that the laser is capable of inducing single photon ionization of the target atoms differentiates the energy deposition mechanisms of these plasmas from those of conventional laser-created plasmas. The set-up used to image plasmas generated with the focused soft x-ray laser beam is illustrated in Figure 11.

![Figure 11. Experimental set-up used to generate a plasma with a focused soft x-ray laser beam and image it.](image)

Focusing of the beam of the 46.9 nm capillary discharge laser was again accomplished with an spherical multilayer coated mirror (\(R=10\text{cm}, \text{ reflectivity } \sim 42\text{ percent}\)). Imaging of the plasma VUV/soft x-ray radiation onto a MCP/CCD detector with \(~14\times\) magnification was accomplished using a second spherical multilayer coated mirror (\(R=20\text{cm}\)). Soft x-ray laser pulses of approximately 0.35 mJ and 1.5 ns duration were used in the experiment. Figure 12 shows the images of plasmas generated by soft x-ray laser excitation of carbon, aluminum, tin, and copper targets. A Soft x-ray emitting plasma region of \(~100\mu\text{m}\) is observed. The results clearly demonstrate the creation of plasmas with a focused soft x-ray laser beam. Future work will include emission spectroscopy to study the plasma characteristics.

![Figure 12. Images of the soft x-ray/VUV emission from soft x-ray laser-created plasmas in C, Al, Cu and Sn.](image)
5. Conclusions

In summary, capillary discharge-pumped lasers are the first tabletop soft x-ray lasers to reach a level of development that allows their routine use in numerous applications. The average coherent power per unit of spectral bandwidth of the Ne-like Ar laser is similar to that of a third generation synchrotron beamline, and its high peak spectral brightness makes it one of the brightest sources of soft x-ray radiation. The proof of principle experiments described above show that tabletop capillary discharge lasers are a powerful source of coherent short-wavelength radiation that can impact numerous fields.
