Abstract

We have developed a compact, 14.7 nm, sub-5 ps X-ray laser source at Lawrence Livermore National Laboratory (LLNL) together with a Mach-Zehnder type diffraction grating interferometer built at Colorado State University for probing dense, high intensity laser-produced plasmas. The short wavelength and pulse length of the probe reduces refraction, absorption effects within the plasma and minimizes plasma motion blurring. This unique diagnostic capability gives precise two-dimensional (2D) density profile snapshots and is generating new data for rapidly evolving laser-heated plasmas. A review of the results from dense, mm-scale line focus plasma experiments will be described with detailed comparisons to hydrodynamic simulations.

Keywords: Interferometer; Laser-produced plasmas; X-ray laser; X-ray optics

1. INTRODUCTION

Interferometry using optical wavelength laser beams was established as a powerful technique to probe dense plasmas within a few years of the invention of the laser (Alpher & White, 1965). Further development of the technique including utilizing a shorter wavelength, 4ω harmonic at 266 nm wavelength, and short duration, 15 ps, for the probe beam, was important to determine the electron density profile steepening at high laser intensities for laser-produced plasmas (Attwood et al., 1978). The short pulse duration was essential for probing close to the target surface to freeze plasma motion. This trend to produce shorter wavelength probes was extended mainly to allow access to large plasmas at high density with less deleterious effects of absorption and refraction that strongly limit the applicability of visible or UV probes. The first soft X-ray laser interferometer was demonstrated by Da Silva et al. (1995) using the Nova high power laser-generated 15.5 nm Ne-like Y laser with a multi-layer coated beam splitter Mach-Zehnder interferometer. Large 1-mm-scale plasmas were probed to an electron density as high as 2 × 10^{21} cm^{-3} to within 25 μm of the initial target surface.

Recently, Rocca et al. (1999) established the 46.9 nm Ne-like Ar capillary discharge X-ray laser as a tabletop interferometer tool using at first Lloyd’s mirror and then Mach-Zehnder diffraction grating instrumentation (Rocca et al., 1999; Filevich et al., 2000). Further benefits can be achieved by going to shorter wavelengths if this can be combined with short pulse duration. The transient gain X-ray lasers have been shown to operate with small tabletop lasers of less than 10 J pump energy. It is possible to produce Ni-like ion 4d–4p transition, 14.7 nm wavelength X-ray lasers in the saturation regime with greater than 10 μJ output energy, and at a high repetition rate of 1 shot per 4 minutes (Dunn et al., 2000). This is sufficient output for applying tabletop, picosecond X-ray laser interferometer to laser-produced plasmas (Smith et al., 2002; Filevich et al., 2004). At this wavelength the critical density n_{crit} is 5.1 × 10^{24} cm^{-3} and so allows the probe to access much higher density plasmas. Further progress in expanding the technique to different
plasmas together with a better understanding of the X-ray source characteristics are reported in this paper.

2. DESCRIPTION

Details of the techniques to generate this X-ray laser (XRL) source on the LLNL compact multipulse terawatt (COMET) laser can be found elsewhere (Dunn et al., 2000; Smith et al., 2002). For these experiments, the short pulse pumping conditions are optimized to give both strong output, and 5 ps X-ray layer pulse duration by using a 6.7 ps laser pumping pulse (Dunn et al., 2003). The pulse duration of the X-ray laser probe takes a snapshot image of the plasma to be probed and determines the temporal resolution for the interferometer. The Mach-Zehnder type interferometer for the 14.7 nm, picosecond duration X-ray laser, uses diffraction gratings as beam-splitters to generate and recombine the two beams (Filevich et al., 2000, 2004). The gratings diffracting the X-ray laser at grazing incidence angles use well-established technology, have high throughput and are robust. This makes the diffraction grating interferometer (DGI) well matched to soft X-ray laser lines over a broad spectral range, including the Ni-like ion Pd 4d–4p X-ray laser at 14.7 nm wavelength. The X-ray laser output is relay imaged to the plasma to be probed using two high reflectivity Mo:Si multilayer coated mirrors. A normal incidence spherical mirror and a 45° flat mirror controlled by a stepper motor are used to align the beam under vacuum to the instrument. This has two advantages: it maximizes the X-ray laser fluence at the plasma and minimizes the steering of the beam due to variations in the XRL deflection angle as it exits the plasma. One major difference between this work and earlier X-ray laser interferometer (Da Silva et al., 1995) is that with the 100× lower output available here, a substantial fraction of the X-ray laser beam is used to probe the plasma. One consequence is that this produces more constraints to the degree of overlap of the beams and spatial coherence of the source for the experiments reported here.

The first Au-coated grating G1, with 900 l/mm groove spacing, splits the XRL into a 0th order (plasma probe) arm and a 1st order (reference) arm, Figure 1. The grating blaze angle and geometry have been designed to give equal reflectivity of ~25% in each arm. The two orders are reflected by the long Au-coated mirrors L1 and L2 to overlap the arms onto the second grating G2. The plasma to be probed is placed in the 0th order beam at the position between G2 and L1. The spherical multilayer mirror IM with 25 cm focal length, after G2, images the plasma and relays the beam via the output Au-coated mirror L3 to the back-thinned charge-coupled device (CCD) camera. The total throughput of the instrument before the imaging optic IM is ~12%.

A second ruling of 16 l/mm is machined vertically offset on G1 and G2 substrates so that the instrument can be pre-aligned with an 827 nm infra-red (IR) diode laser. The IR laser has an estimated coherence length of ~300 μm which is similar to the ~400 μm 1/e half width longitudinal coherence recently measured for the X-ray laser using a 6.7 ps pumping pulse (Smith et al., 2003). The IR laser is used to adjust various optics to make the two arms equal in length, and for generating interference fringes. High quality 14.7 nm soft X-ray interference fringes have been generated with visibility exceeding 0.8. The magnification of the

imaging system is set to give high X-ray laser fluence on the
detector, effective working area at the plasma as well as
good spatial resolution. The soft X-ray laser beam at the
target position is imaged onto a 1.33 × 1.33 cm² CCD with
1024 × 1024 pixels of 13 × 13 μm² dimensions. Magnifi-
cation of 22 times is routinely used which gives a field of
view of the plasma of ~600 × 600 μm². The pixel-limited
spatial resolution is 0.6 μm with the overall spatial resolu-
tion of the instrument determined to be 1–2 μm.

3. RESULTS

We report results from several laser-produced plasma exper-
iments that demonstrate probing long plasma columns gen-
erated by line focus incident on a 0.1 cm long Al slab target
heated by the 600 ps full width at half maximum (FWHM),
1054 nm laser of COMET. A maximum energy of 3 J was
available to produce a short line focus of 12 μm (FWHM) ×
0.31 cm long using a combination of a cylindrical lens f =
200 cm and an off-axis parabolic f = 30 cm. This corre-
sponds to an incident laser intensity of ~10^{13} Wcm⁻². The
target rotation angle was carefully adjusted to ensure that
the interferometer probe was parallel to the surface. The
beams that form the X-ray laser and the second plasma to be
probed come from the same oscillator and are synchronized.
A delay line on the plasma-forming beam was adjusted for
the X-ray laser to probe the plasma at various times from
\( \Delta t = -0.5 \) to +3.0 ns, where \( \Delta t = 0 \) refers to the peak of the
heating pulse. The absolute timing of the heating and X-ray
laser beams was better than 100 ps while the X-ray laser
pulse duration was ~5 ps.

Figure 2(a) shows one of a sequence of X-ray interfero-
grams of the 0.1 cm long Al target recorded at +0.86 ns after
the peak of the laser heating pulse. The 0.1 cm dimension of
the plasma column is off the page in the direction of the X-
ray laser probe. It should be noted that there is very strong
lateral expansion of the plasma along the target, vertical axis
in Fig. 2(a), that is present almost immediately after the start
of the laser pulse. So in addition to the expected strong
expansion perpendicular to the target surface there is a very
strong sideways component. A second feature is the small
on-axis dip close to the target surface that is also observed in
earlier time interferograms. This feature has not been seen
on previous experiments at our laboratory with a wider line
focus. The ability of the X-ray laser interferometry to probe
close to the target surface allows this feature to be clearly
seen. Simulations with the LASNEX hydrodynamics code
(Zimmerman & Krueer, 1975) indicate that this is formed
early on during the rising edge of the laser pulse and may be
a result of the small line focus creating hot plasma condi-
tions in a very localized region close to the target surface.

The extracted 2D electron density profile from the inter-
ferogram is shown in Figure 2(b) and for comparison the
2D LASNEX hydrodynamic simulations at +0.8 ns, Fig-
ure 2(c). The laser pulse shape and focal spot shape are used
in the simulations in order to model the experimental con-
ditions as closely as possible. The overall agreement is good
with some small differences on the sides of the plasma.

Figure 3 shows an on-axis lineout of the experimental data
and simulations with generally good agreement. The maxi-
mum electron density measured is 4 × 10^{20} cm⁻³ close to
the target surface where the fringe visibility becomes diffi-
cult to observe in the last 10 μm. It should be noted that at
times later than +1 ns there is a reversal of the fringe
direction close to the target surface (Filevich et al., 2005;
Nilsen & Scofield, 2004). This is understood to be the
contribution from the presence of low ionization stage bound
electrons that for aluminum plasmas change the sign of the
gradient of the index of refraction. This requires careful
 determination of the ionization of the plasma to interpret the
fringe shifts (at late times) in extracting the electron density
from the interferograms. It also makes the interferometry a
very sensitive tool for probing low temperature plasmas.

A second run was carried out where a similar laser pulse
was tightly focused at the center of the bottom of an Al
groove of dimensions 100 × 200 × 1000 μm³ (H × D × L)
machined by a diamond saw. This has the effect of confining the expansion of the plasma. The long axis of the line focus is aligned along the groove length. Figure 4, top image, shows the interferogram inside the groove before the laser pulse. The lower image, taken at 1.6 ns after the peak of the pulse, already shows a number of processes occurring. The plasma has expanded and hit the groove walls where there is now local heating in the corners and a plasma jet stream out of the groove. At ~1 ns, the electron density is determined to be $1.2 \times 10^{21} \text{cm}^{-3}$ in the groove corners which is higher than the critical density of the laser heating beam. It should be possible to measure significantly higher electron densities with this technique by heating more target mass using higher energy beams focused to high intensity.

We have recently performed experiments to study long laser pulses incident in a tight focal spot on small lollipop targets to complement the lower intensity line focus plasma column experiments. Figure 5 shows two 14.7 nm soft X-ray interferograms of a 50 μm diameter lollipop target irradiated with a 20 J, 5 ns, 1064 nm flat top pulse generated by the JANUS laser. This beam is focused to 20 μm (FWHM) diameter spot that corresponds to an intensity of $10^{15} \text{Wcm}^{-2}$ on target. The target is constructed by etching a Si wafer 50 μm thick then coating on both sides with 7 μm parylene-C. The interferogram before the laser pulse is shown in Figure 5(a). As in the previous examples, the target is viewed from the side. Figure 5(b) at +4.8 ns, very close to the end of the laser pulse, shows the laser beam is incident from the right with strong plasma self-emission clearly visible on that side. The fringe shifts on the backside (left) of the target indicate plasma formation. The interferometer has been setup so that the plasma will induce fringe shifts toward the left. The lateral plasma expansion on the back surface is slightly larger than 100 μm with some indication that the target has disintegrated at the top. It is interesting to note that the plasma appears on the backside at fairly early times in the pulse, and is expected to be mainly produced by plasma from the front surface streaming round the target, rather than back surface release from laser-induced shock. While it would require Abel inversion to de-convolve the electron density profile, an estimate of the electron density can be deduced from the fringe shifts and plasma size. We estimate that the electron density is in excess of $5 \times 10^{21} \text{cm}^{-3}$ for Figure 3(b) but a full analysis is required with a more symmetrical 2D fringe pattern for more precise density measurements.

4. CONCLUSIONS

Picosecond X-ray laser interferometry at 14.7 nm of laser-produced plasmas has been successfully demonstrated using a Mach-Zehnder diffraction grating interferometer. The combination of short wavelength and short pulse duration of the source and the high throughput of the instrument presents a unique diagnostic capability to study large, hot, dense plasmas. This technique can be applied to different target plasma geometries and has the potential to benchmark 2D hydrodynamic simulations codes under a wide range of condi-
tions. In addition to extracting 2D density information from the interferograms, the technique can also quantify the degree of plasma ionization in low temperature aluminum plasmas. Plasmas created with laser pulses over 100 J of energy, and intensities up to \(10^{15} \text{ W cm}^{-2}\) have been studied, and soft X-ray interferograms have been recorded with \(\sim 1 \mu\text{m}\) spatial resolution close to the target surface. It is particularly important to note that the source, technique and instrumentation can be scaled to shorter wavelengths and can be applied to large plasmas generated on the National Ignition Facility and other large-scale, very dense plasmas. Further data analysis and simulations are in progress and will be reported shortly.
